1 This paper refers to EU15, that is it does not consider the 10 countries which joined in 2004.
Abstract

In the current debate on the European Union (EU) fiscal rules there is a widespread consensus on the need to place more focus on government debt and long-term fiscal sustainability in the surveillance of budgetary positions. More specifically, pension developments should be taken into account in assessing fiscal sustainability. The way to make this operational has not yet been defined. First, the paper examines the pension expenditure projections available in EU countries and their use in the assessment of fiscal sustainability. While acknowledging the progress in the availability and quality of projections, the paper notes that their comparability is still unsatisfactory. Any mechanical use of existing pension expenditure projections should therefore be avoided. Secondly, the paper examines the different definitions of pension liabilities and their potential role in the EU fiscal framework. It argues that pension liabilities may bring a clearer understanding of the impact of fiscal policies, may provide a measure of the cost of terminating pay-as-you-go pension schemes and may be useful for the measurement of deficits computed on an accrual basis. However, the level of pension liabilities does not provide indications concerning the sustainability of pension schemes and their effects on public budgets. Pension liabilities should not be added to conventional debt. The paper argues that both pension expenditure projections and estimates of pension liabilities can complement the deficit and debt indicators currently used in the EU fiscal rules. The paper concludes by pointing to the need to improve some technical and organisational aspects concerning age-related expenditure projections, such as the independence of forecasters, the transparency of projections and the homogeneity of methods. Improvements in the quality of pension expenditure projections would also enhance the quality of estimates of pension liabilities.
1. Introduction

The search for rules and procedures that ensure sound budgetary positions has been at the core of the development of the fiscal framework of the European Economic Monetary Union (EMU). Since the early 1990s budgetary discipline has been recognised as an essential condition for the success of EMU. In 1992 the Treaty of Maastricht set the deficit and debt conditions for access to EMU. The Stability and Growth Pact (SGP), adopted by the European Council in Amsterdam in June 1997, complemented the Treaty with a view to reconcile permanent restraint of deficit and debt levels with margins for fiscal stabilisation policies. The Pact also strengthened the monitoring procedures accompanying the quantitative rules.

Overall, the European Union (EU) adopted a pragmatic solution which can increase the scope for stabilisation policies and can contribute to allowing EU countries to meet the budgetary pressures caused by the ageing of their population on a sounder fiscal position.\(^1\) The chosen solution reflects, *inter alia*, the ambiguity of the economic theory on fiscal sustainability and the multinational dimension of EMU.

In recent years, several suggestions to assign a greater role to long-term sustainability in the EMU framework have been put forward. A widespread consensus on the need to place more focus on government debt and sustainability in the surveillance of budgetary positions seems also to emerge from the current debate on the EU fiscal rules. This point has been raised by the European Commission, the European Council, the IMF and the OECD. According to these institutions, a properly grounded sustainability analysis should take into account the effects of population ageing on public finances. In particular, pension expenditure developments should be considered.

Future expenditure trends can be integrated into fiscal sustainability analysis in many ways. This paper aims at contributing to the current debate by exploring the role of pension expenditure projections and of that of pay-as-you-go (PAYG) pension liabilities.

Both indicators have attracted a considerable interest in the policy debate. The availability of accurate projections is now recognised as a necessary condition for the efficient design of social policies and, more specifically, of pension reforms. Over recent years the resources assigned to them have been substantially increased. Projections are now available on a regular basis in most developed countries. It is rare that a major pension reform is drafted without a projection exercise concerning its long-term effects. In parallel, it has frequently been argued that pension liabilities should be taken into account when evaluating the state and the perspectives of public finances.\(^2\) It has been claimed that “the strains that higher dependency ratios will impose on budget policies can be seen by examining the present value of future net liabilities of the pension systems in the major industrial countries.” (IMF, 1993, p. 56).

The paper notes that sustainability issues should be primarily addressed by considering the projections concerning the pension expenditure-to-GDP ratio and the contribution rate that assures the cash balance of pension schemes. However, in view of the still unsatisfactory comparability of pension expenditure projections (across countries and across research centres), the paper suggests to avoid any mechanical use of existing projections in the EU fiscal framework. It also suggests improving some technical and organisational aspects concerning age-related expenditure projections, such as the independence of forecasters, the transparency of projections and the homogeneity of methods.

After having examined the different definitions of pension liabilities and their economic implications, the paper argues that the level of pension liabilities does not provide indications concerning the sustainability of

---

---
current pension policies and the effects of pension schemes on public budgets. It also argues that pension liabilities should not be added to conventional debt. Moreover, current estimates of pension liabilities present the same problems affecting the quality and comparability of pension expenditure projections.

Rather, the paper suggests complementing the current deficit and debt indicators with additional indicators concerning future budgetary developments and a broader definition of public sector liabilities. In this context, estimates of pension liabilities may represent a useful complement to conventional fiscal indicators. They may bring a clearer understanding of the impact of fiscal policies, may provide a measure of the cost of terminating PAYG pension schemes and may be useful for the measurement of deficits computed on an accrual basis.

Section 2 briefly surveys the approach to fiscal sustainability taken by the EU. Section 3 examines the pension expenditure projections available in EU countries. Section 4 considers the different definitions of pension liabilities and the information that they provide. Section 5 overviews the existing estimates concerning pension liabilities. Section 6 compares pension expenditure projections and pension liabilities estimates in view of the assessment of fiscal sustainability in the EU framework. Section 7 highlights further progress needed in both pension expenditure projections and pension liabilities estimates. Section 8 concludes.

2. Fiscal sustainability in the European Union

2.1 The EU approach to sustainability. – Fiscal soundness is the main objective of EMU rules. In defining a fiscal framework aimed at safeguarding the credibility of the single monetary authority and at avoiding monetary policy to be overburdened in its pursuit of price stability, the EU was confronted with several problems.

First, while the intuition is clear (a sustainable policy must ultimately avoid insolvency), the analytical and operational definition of sustainability is not straightforward. Economic theory has proposed different conditions for sustainability (from a non ever-rising tax rate to an inter-temporal discounted budget constraint). Furthermore, also the operational indications are not straightforward. For example, even if we agree that in order to be sustainable the debt-to-GDP ratio must be stable, we have no indication as to which stable level is sustainable. To assess the maximum sustainable debt level one should consider the interaction of public finance and the economy (and there is no agreed upon theory on that). Moreover, difficulties arise also about the definition of the variables to be used in the analysis (should gross or net debt be used? how should the deficit be measured?).

Second, the rules were to be applied to a group of countries, each retaining fiscal sovereignty. A general commitment to carry out sound fiscal policies was not sufficient. Monetary stability represents a public good to which all governments contribute by maintaining sustainable budgetary positions. As with all public goods, there is an incentive for each government to exploit the benefits accruing from the discipline of others without contributing itself. This creates a double cost for the other governments: the free-rider’s excessive indebtedness can put pressure on interest rates to rise and it can also result in bankruptcies requiring bail-outs.

Third, in the early 1990s the deficit and debt positions differed significantly across EU countries. Some countries were clearly in unsustainable fiscal positions, with high and rising debt and deficit ratios and large

---

3 The rationale for EMU rules is discussed, e.g., in Buti and Sapir (1998) and in Brunila et al. (2001).
expected expenditure increases. In order to induce a sharp change in the budgetary policies of these countries, tight numerical parameters were required. Since it was politically difficult to differentiate the conditions set for accession to EMU from those envisaged to be a permanent feature of the Union’s fiscal framework, the former substantially affected the latter.

When confronted with these difficulties, the EU adopted a pragmatic approach. The Treaty of Maastricht defines sustainability as non-violation of arbitrarily predetermined parametric standards, which are 3 and 60 per cent of GDP for deficit and gross debt respectively. The Treaty makes no distinction between current outlays and investment. The deficit ceiling is reminiscent of the constant deficit assumption analysed by Domar (1944). Apparently conscious of the partial equilibrium nature of Domar’s results, the debt ceiling avoids convergence to high levels of debt.

Later the SGP introduced a medium-term target of a position “close to balance or in surplus” thus tightening the deficit rule while also trying to reconcile it with counter-cyclical fiscal policy. The equilibrium value of the debt ratio depends on the numerical definition of this position, which in turn is to be determined so as to allow enough room for stabilisation policy while avoiding to breach the 3 per cent deficit threshold during cyclical downturns.

The implied policy stance may often be tighter than what is needed for sustainability by whatever definition. If EU countries stick to the close-to-balance guideline, they will converge to equilibrium debt levels much below the 60 per cent threshold. Some countries might even end up not having any debt and actually accumulating assets over time. One may question whether a theory-based benchmark, if available, would have implied these results. No definition actually envisages the abolition of public debt.

The SGP combines the traditional requirement to balance the budget with the call for letting the budget adapt to cyclical conditions. It also recognises the role of extraordinary finance.

The definition of the debt and deficit indicators relevant for EMU’s fiscal rules takes into account the need to ensure comparability of national statistics and to allow a regular surveillance process. Methodological choices were made with pragmatism. The sector of reference is general government, as defined in the European System of Accounts (ESA) under the responsibility of Eurostat.

Debt and deficit are respectively defined as the total of gross general government liabilities at nominal (face) value and as the balance of non-financial transactions (as defined in the ESA) of general government. The choice of a gross measure for debt depends, among other reasons, on data availability, since data on assets

---

5 This was due, *inter alia*, to the possibility of other countries joining EMU at a later stage. Moreover, it was clear that the reduction of debt to acceptable levels required long periods of fiscal restraint.

6 Article 121 requires “the sustainability of the government financial position” for a country’s eligibility to EMU. Article 104 defines the criteria to evaluate sustainability by means of reference values for deficit and debt to GDP ratios. The economic rationale of the parameters has indeed been questioned, see Buiter *et al.* (1993) and Eichengreen and Von Hagen (1996) for a discussion.

7 However article 104 includes capital outlays among the relevant factors for the assessment of Member States’ budgetary positions.

8 Leeftink (2000) tests for the consistency of the two objectives, while Lindh and Ohlson (2000) doubt the capability of the Pact to ensure that budgetary policy reacts symmetrically to positive and negative cyclical developments.

10 The cyclical events to be considered extraordinary are explicitly defined.

11 Financial instruments to be considered and accounting criteria to be used are also specified in the ESA. For an extensive analysis see Mink and Rodriguez-Vives (2004). Some problematic aspects are examined in Balassone *et al.* (2004).
are not always available and their quality is often poor. However, this solution comes at a cost. For instance, the definitions adopted for debt and deficit are not consistent (i.e. the ESA deficit does not coincide with the change in debt).  

Reference to a common protocol is obviously helpful for international comparison. Using definitions in line with those adopted by Statistical Offices makes immediately available past data and allows to base forecasts on the most detailed databases.

### 2.2 Assessing fiscal sustainability in the EU.

The EMU fiscal framework does not make long-term sustainability indicators unnecessary. Due to, *inter alia*, demographic changes, compliance over the short and medium term does not necessarily ensure compliance over the long term. There is a need for indicators highlighting prospective deviations and measuring their size and timing.

The issue of long-term sustainability has gradually gained importance in the assessment and design of fiscal policy. In a report on the co-ordination of economic policies to the European Council held in December 1999, the Ecofin noted the need for an explicit reference to the sustainability of public finances. The Ecofin called for a broadening of the issues covered by the Stability and Convergence programmes to medium- and long-term sustainability problems. Subsequently, several European Councils highlighted the population ageing problem and, in particular, its implications for maintaining adequate and sustainable pensions. In particular, in March 2001 the European Council held in Stockholm established a three-pronged strategy to tackle the budgetary implications of ageing populations. The strategy envisages raising employment rates (especially amongst women and older workers), reducing public debt and reforming pensions and health-care systems.

The Council also agreed that long-term fiscal sustainability should be regularly reviewed. The review would be done under the Broad economic policy guidelines and in the Stability and Convergence programmes presented each year by Member States. This decision extended the framework of the EU multilateral surveillance and introduced a specific commitment for the Commission to examine the long-term sustainability of public finances.

In view of the lack of a consensus on the definition of sustainability of public finances, in its assessments of the Stability and Convergence programmes, the European Commission follows a pragmatic approach. It addresses three policy questions: (i) Given the projected budgetary implications of population ageing, will the budgetary requirements of the Maastricht Treaty be respected on the basis of current policies? (ii) Are the medium-term budgetary targets outlined in the programmes compatible with an improvement of the sustainability of public finances? (iii) What are the main policy challenges facing Member States and what reforms should be envisaged?

In November 2002, in its Communication on *Strengthening the coordination of budgetary policies*, the European Commission suggested that sustainability concerns should be explicitly taken into account when assessing the budgetary positions of Member States under the SGP. To this end, greater weight should be attached to government debt ratios in the budgetary surveillance process; more specifically, the debt criterion set by the Treaty of Maastricht should be made operational. In addition, the assessment of the sustainability of public finances – as part of the Stability and Convergence programmes – should be upgraded, with firm policy conclusions as to whether the budgetary policies are ambitious enough to meet the challenge posed by ageing populations.

---

12 In particular, with the adoption of the 1995 version of the ESA, deficit figures are based on accrual accounting.

13 The European Council held in Lisbon in March 2000 stressed the need to study the future evolution of social protection from a long-term perspective, with particular attention to the sustainability of pensions.

14 This is done along the lines developed in European Commission (2004a) report.
In its most recent contribution to the debate on strengthening the implementation of the SGP, the Commission also notes that in defining the required debt reduction it is necessary to take into account the need to ensure prudent debt ratios before the impact of ageing fully takes place. Moreover, the Commission stresses that a better knowledge of the factors influencing long-term sustainability of public finances such as pension and contingent liabilities and assets is required. Further deepening of the comprehension of these developments would help to integrate them better into the fiscal framework.

There are several ways in which more attention can be placed on the factors that may influence the medium and long-term dynamics of the debt. This paper explores two main possibilities: the use of pension expenditure projections made at the EU level by each Member State and the use of pension liabilities.

3. Pension expenditure projections in the European Union

This section examines the pension expenditure projections available in EU countries, at both the national and the international level, their use in the EU fiscal framework and some problematic aspects concerning their quality and comparability. Box 1 provides some background information concerning the evolution of long-term expenditure projections and some underlying technical problems.

Box 1

Long-term public expenditure projections

Long-term fiscal projections were carried out as early as 1942 when a 30-year estimate of social expenditure in the UK was included in the Beveridge Report. However, it is from the mid-1980s, when it became apparent that Western countries were experiencing major changes in their demographic structure, that an increasing number of studies have examined the long-term prospects for public budgets (Heller, 2003). This development is related to the growth of legislated policy commitments in social insurance, to better capacity of modelling and simulating economic trends and to the public debate on demographic issues.

The studies examining the prospects of expenditure programmes focus on budget items particularly dependent on population age structure, such as pension, health and education spending. The basic intuition is that citizens of different sex and age groups receive from government different amounts of services and transfers. In these studies data on per capita public spending for different age groups and for different budgetary items are combined with demographic projections. Some studies only consider the effects of demographic changes, while others also try to capture some non-demographic factors such as pension scheme maturation and long-term trends towards higher health expenditure.

Mechanical projections of the effects of demographic changes. – The most basic approach provides estimates of the effects of demographic changes on public expenditure under the assumption that age-related per-capita expenditure levels remain constant over the projection period in real terms or in per-capita GDP terms. In other words, it is assumed that present standards of transfers and services are maintained for all population-age groups and that there is no behavioural response from governments or households to demographic changes and to their budgetary effects.

Age-related expenditure profiles thus form the building block of studies evaluating the impact of changing demographics on public expenditure. They are computed by estimating the average amount spent for members of each sex and age group on the basis of administrative data or economic surveys (Franco and Munzi, 1997). The profiles for the base year can be combined with the future expected structure of the population in order to evaluate the mechanical impact of demographic changes on public spending.

Expenditure profiles for different budgetary items can be projected into the future on the basis of the assumption that expenditure for the members of each age group increases at a yearly rate equal to the rate of growth of GDP per worker

---

16 A contingent liability can be defined as a public sector action that determines cash expenditure only if and when a certain event takes place.
or to the rate of growth of per-capita GDP. The former assumption is reasonable for expenditure items mostly represented by wages. The latter is reasonable for transfers. The two assumptions lead to different estimates when the ratio of workers to citizens changes.

Estimates combining data on per capita expenditures for different age-groups and for different budgetary items with demographic projections are only indicative measures of the likely effects of demographic changes on public expenditure, since they do not take all relevant effects of demographic changes into account (OECD, 1988a).

First, mechanical estimates are based on the implicit assumption that the marginal cost of providing services to a smaller or a larger number of individuals in each age group in the future will be equal to the present average cost of these services. In other words, it is assumed that there are no economies or diseconomies of scale in the production of public services. Second, mechanical estimates implicitly assume that demographic changes do not modify present age-related per-capita expenditure levels, while they can actually affect them through many different channels (Pearson et al., 1989). They can also affect productivity trends, wage rates and saving ratios. The use of current per capita age-profiles to project expenditure levels is particularly problematic for health care (see Zweifel et al., 1995). Moreover, it should be stressed that demographic change is just one of the several factors affecting public expenditure dynamics. The contribution of mechanical estimates of the effects of demographic changes to the assessment of the prospects for public expenditure is therefore necessarily limited.

**Projections considering non-demographic changes.** – While several economic, political and social factors can obviously affect the dynamics of per-capita transfers and services, the studies examining the prospects of age-related expenditure usually focus only on three specific factors: the effects of changes introduced in legislation, but not yet embodied in present expenditure profiles; the effects of the continuation of structural expenditure trends; and the effects of structural changes in the economy and society. These factors are considered because they are consistent with a constant policy approach, while there is usually no attempt to predict the effects of changes in behaviours and policies.

The effects of changes introduced in legislation, but not yet embodied in present expenditure profiles, are particularly relevant for pension expenditure projections (OECD, 1988b). The continuation of structural expenditure trends is especially relevant for health care expenditure projections. In several countries the health sector has for long periods recorded a price deflator substantially higher than the GDP deflator and a tendency towards a continuous increase in per capita consumption (OECD, 1993). Projections can also forecast the effects of structural changes in economic structure, labour market and household composition. The basic idea is that entitlement to and provision of public transfers and services depend on certain characteristics of citizens.

Projections integrating the mechanical effects of demographic changes with estimates of some additional factors influencing pension and health expenditure were produced by the IMF in 1986 with reference to the seven main Western economies (Heller et al., 1986). The overall impact of ageing populations on government budget was also examined in the studies carried out by OECD in 1995-96 (see Leibfritz et al., 1995, Roseveare et al., 1996, and OECD, 1996) and by the European Commission in 1997 (see Franco and Munzi, 1997). Growing awareness of population ageing has also led to a substantial increase in the resources devoted to national long-term public expenditure projections.

To allow for comparability among the projections of different countries, some international bodies have begun to sponsor and co-ordinate forecasting exercises in which national authorities make projections based on uniform assumptions. These exercises make the various countries’ forecasts more comparable, though leaving responsibility for the projections to the national authorities which have the best institutional and statistical knowledge (see Economic Policy Committee, 2000, 2001, 2003, and OECD, 2001).

**Projection models.** – The forecasting models currently in use were developed gradually as needs for knowledge emerged. They employ a wide variety of methodologies. In moving from the mechanistic projection of changes in the age-structure of the population to the assessment of several economic and social factors, the models have gradually become more complex. The projection of individual expenditure items has frequently been replaced by a wider analysis of the evolution of the public finances as a whole in a macroeconomic framework.

The models are generally deterministic and based on microdata such as sample surveys of the population or administrative data supplied by social security administrations. With a view to past performance, assumptions are made on the level of fertility, change in mortality, immigration levels, wages, unemployment rates, productivity and inflation rate. Models are often organised in different modules: the first one projects the evolution in population; the second one aims at grouping people on the basis of their characteristics; the third one actually projects long-term age-related.
Pension expenditure projections in the EU. – All EU countries have developed models for projecting pension spending. This is a relatively recent development: till the mid-1990s the availability of projections in EU countries was very uneven and their quality was sometimes unsatisfactory.\(^\text{17}\) The development of better forecasting models has been boosted by the decision to start joint projection exercises at the EU level (see Box 2).

Projections are usually carried out for periods of thirty to fifty years, although occasionally they extend to seventy-five years. Trends in expenditure items are generally evaluated in terms of their incidence on GDP or in terms of some synthetic indicator (as, in the case of forecasts of pension outlays, the equilibrium contributory rate). National projections primarily cover first pillar pension schemes, including private and public sector employees and self-employed workers. A full coverage appears only in a subset of EU countries (EPC, 2003). Belgium, Denmark, Finland, Ireland and Sweden have in their projections a full coverage of all social benefits, both in cash and in kind. This allows them to have a broad picture of the impact of ageing populations on the expenditure side of public budgets.

In most EU countries national long-term projections are regularly updated to take into account changes in legislation, in the economic context and in the demographic scenario. In Denmark, Sweden and the UK projections are updated more than once a year; in Belgium, Germany and Italy once a year.\(^\text{18}\) Updates are less frequent in Austria (once every three years), Ireland (once every two years) and in the Netherlands (once every four years). Irregular updating is being done in Finland, France and Portugal. In Greece the National Actuary Authority, which has been recently established, is in charge of producing long-term projections on a regular basis.

---

**Box 2**

Pension expenditure forecasting exercises conducted by national institutions in the EU

---

17 For a review of the projections available at the national level in the mid-1990s in the EU Member States, see Franco and Munzi (1996).

18 In Germany this applies to projections performed for the general statutory pension scheme, whereas projections for the civil servant’s pension scheme are updated once in every legislative period.
Over the past decade, all EU countries have developed models for forecasting the financial situation of public pension systems. A review of the forecasts on pension outlays for the period 1995-2030 carried out by public institutions in the fifteen EU Member States in the early 1990s found an average increase in the ratio of pension spending to GDP ranging between 3 and 4 points, i.e. about a tenth of a point per year (Franco and Munzi, 1996). The exercises pointed to a significant increase in spending not only in many countries that had not yet reformed their pension systems (Belgium, Denmark, Ireland, Luxembourg and the Netherlands) but also in some countries that had already enacted major reforms (Finland, France and Germany). Relatively limited increases in spending were expected in Italy, Portugal, Spain, Sweden and the United Kingdom. In many countries the ratio of pension expenditure to GDP in 2030 was projected to be between 15 and 20 per cent.

There is a tendency towards a regular release of projections. In the United Kingdom, since 1975 the Government Actuary’s Department has revised the long-term forecasts of the National Insurance Scheme every five years. One section of each forecasting report describes the changes from the previous set of projections. In Germany, the Federal Government releases 15-year projections every year. The need for regular forecasts (every five years) was acknowledged in Ireland in the 1993 report of the National Pensions Board and in Spain by the Toledo Pact of 1995. In Italy, forecasting activity has found increasing legislative support. A law in 1988 established that technical reports on draft bills concerning pensions must include projections covering at least ten years. In 1995 it was further decided that starting in 1998 the annual Economic and Financial Planning Document must have a special section projecting pension spending for the subsequent decade.

In the last few years, a number of countries produced new estimates of pension spending trends. In some cases they are aimed at simply evaluating the future pension expenditure on the basis of existing conditions (Blanco Moreno et al., 2000); in others, they are directed to the enactment of further reforms (Charpin, 1999). In still others, they are intended to help determine the best policy for dealing with the problems posed by population ageing.

In the Netherlands, the Bureau of Economic Policy Analysis (2000) forecasts pension spending as part of an exercise designed principally to project the total income of retirees, including private retirement plans and investment income. The report estimates the composition of these incomes and the income replacement rate vis-à-vis earnings from labour, for different population deciles in 1996 and 2045. It examines the relation between pension system and labour market, specifically for people aged 60 to 66 and it evaluates the overall prospects for the public finances, also considering the implications of alternative economic policy scenarios for the various generations.

Across countries there are also differences concerning forecasters. In particular, the forecasting process may involve either formally or informally several actors: social partners, independent experts, social security institutions and ad hoc public bodies (committees, working groups, etc.). In most countries the assessment of long-term sustainability of public finances is conducted primary by Ministries of Finance or Economy but there are cases where the Social or Labour Ministries or other public institutions are involved.

In EU countries long-term projections are used to set up budgetary medium-term targets, to plan major reforms with an impact on budgetary positions, to project the debt profile and to assess the long-term sustainability of public finances.

---

19 This is the case for Belgium, Denmark, Finland, the Netherlands and Sweden. In the Netherlands, for instance, since long-term projections indicate that the elimination of public debt within this generation would allow covering part of the costs of ageing through interest savings, the medium-term budgetary target is then defined to achieve this result. In Denmark and Sweden projections have been used in setting the medium-term target of 2 per cent of GDP surplus. Belgium and Finland fix
Projections typically include a baseline scenario representing a continuation of current policies, particularly with respect to social insurance legislation (in terms of eligibility conditions and the amount of the benefits), and alternative scenarios for relevant economic and demographic variables. These alternative exercises may also seek to evaluate the impact of specific policy adjustments or of alternative policy assumptions.

Finally, projections are usually deterministic, implying that even when accompanied by stress tests, they confer no sense of the likelihood of any specific scenario taken into consideration. Sometimes, one observes a pairing of assumptions that might yield the most optimistic or pessimistic case but that may be unlikely to occur together.

After some technical work carried out by the Commission, in 1999 a technical working group – the Ageing Working Group (AGW) – was set up to examine the economic and budgetary implications of ageing populations and provide expenditure projections (see Box 3). The AWG provides projections of public expenditure on pensions, on health and long-term care and a number of indicators of long-term fiscal sustainability. The projections involve the use of the forecasting models developed by national authorities but are based on common assumptions on demographic developments and key economic parameters such as labour market developments, productivity growth and real interest rates. The projection exercises increase the comparability of national forecasts, though leaving responsibility for the projections to the national authorities, which have the best institutional and statistical knowledge.

The AWG exercises refer to a current policy scenario which does not necessarily represent the most likely scenario in the Member States’ view but rather the consensus reached in the group as to what would constitute a prudent and reasonable starting point. The AWG estimates are based on the demographic projections prepared by Eurostat on the basis of assumptions regarding fertility rates, life expectancy and migration. Long-run projections for social expenditures are heavily influenced also by assumptions on labour market developments and other macroeconomic variables.

Box 3

Co-ordinated exercises promoted by the European Commission

medium-term targets in order to be consistent with a projection where the budgetary path ensures long-term sustainability, taking into account the likely impact of ageing.

20 Franco and Munzi (1996 and 1997).
21 The Ageing Working Group was set up by the Economic Policy Committee (EPC) of the EU. The group includes experts from national administrations, representatives of the European Commission, the European Central Bank and the OECD.
23 The OECD has co-ordinated similar exercises (OECD, 2001).
24 In Eurostat baseline scenario fertility rates are projected to converge upward to an average of 1.7 for the EU by 2050 (the average EU fertility rate in 2000 stood at 1.5), with most of the increase occurring in the coming two decades. Regarding migration flows, it is assumed a net inward migration to EU countries of about 640,000 people per year (about 0.2 per cent of the total population). Life expectancy is projected to steadily increase over the projection period: for men it is projected to rise from 75 years in 2000 to 80 years by 2050; for women, from 81 to 85.
25 The AWG in Economic Policy Committee (2000 and 2001) used the same assumptions agreed in the OECD projection exercise. Labour force participation rates up to 2010 are based on projections by the International Labour Organisation (ILO, 1997). Thereafter, labour force participation rates are constant for men and rising for women (the latter rates reach in 2050 levels of 5 to 10 points lower than those assumed for men). Unemployment rates are assumed to fall to their structural level by 2005, as defined by the OECD, and to stay constant thereafter. For the EU, this results in unemployment falling to 8 per cent. The AWG agreed that labour productivity growth should converge towards an annual rate level of 1.75 per cent by 2030, although some leeway for higher rates is provided for catching-up countries.
In Economic Policy Committee (2000) the pension expenditure-to-GDP ratio is predicted to rise in all EU countries but the United Kingdom over the coming decades. In some countries the rise is significant. Expenditure peaks are reached at different times. In particular, in the majority of countries the effects of ageing will add 3 to 5 percentage points of GDP to pension expenditure: Austria (3.1 per cent by 2030), Belgium (3.7 per cent, peaking in 2040), Denmark (4.5 per cent, by 2030), Finland (4.7 per cent, by 2040), France (3.9 per cent, by 2030), Germany (4.3 per cent, by 2050 or after), and Ireland (4.4 per cent, by 2050 or after). In some countries the upward pressure is even higher: the Netherlands (6.2 per cent, by 2040), Spain (8.3 per cent, by 2050), and Portugal (6.2 per cent, by 2030). Moreover, the results have been decomposed according to the four explanatory factors driving the projected changes in pension spending: the population ageing effect, which measures the changes in the ratio of persons aged 55 over the population aged 15 to 54; the employment effect, which indicates the changes in the share of population in working age (15 to 64) that is employed; the eligibility effect, which measures the share of the population aged 55 and over that receive a pension; the benefit effect, which captures changes in the average pension relative to output per worker. Sensitivity tests were carried out to gauge the impact of changes in various parameters, i.e. population, participation rate, employment rate, productivity rate and interest rate. A policy simulation based upon the successful implementation of the Lisbon strategy was also carried out compared with the “current policy scenario”.

Economic Policy Committee (2001) builds upon the previous report: for some countries the data provided have been supplemented and in some cases updated to incorporate the impact of recent reforms. Notwithstanding these changes, Economic Policy Committee (2001) confirms the previous results. The projections show that for the EU as a whole, public pension spending is projected to peak in 2040 at 13.6 per cent of GDP from 10.4 per cent in 2000. It should be noted that the projection exercise has only considered pension expenditures and not revenues to pension systems, although some Member States did report data.

According to Economic Policy Committee (2003), the ageing populations will lead to an increase in public spending (including not only pensions but also other age related items) ranging from 0.6 per cent of GDP in the UK to 13.0 in Greece (Table 1). Most of the increase will derive from pensions, health and long-term care spending, whereas savings stemming from education and unemployment benefits will be limited. In particular, public spending on pensions is projected to increase by between 3 and 5 percentage points of GDP, largely driven by the increase in the old-age dependency ratios. Reforms in the 1990s, especially the indexation of entitlements to prices and extension of assessment periods, appear to have mitigated the expenditure increases in some countries. Demographic changes would lead to a rise in public spending on health and long-term care by between 1.5 and 4 percentage points of GDP up to 2050. However, there are upside and downside risks to the projections results, as the impact of non-demographic factors was not explicitly modelled. Public expenditure in education is expected to decline in the next 50 years, but significant savings are projected only in some countries. Using the labour force assumptions, unemployment benefit spending will show very modest decreases in most Member States.

(1) For a summary description of recent reforms, see European Commission (2000a), EPC (2003), and Franco and Marino (2003). The reforms regarded indexing (Germany and Italy), the reference period for calculating the pension award (Spain), the retirement age for women (Austria, Belgium, Germany and the United Kingdom) and the requirements for early retirement eligibility (Austria, Denmark, Germany and Italy).

\(^{(1)}\) The table brings together the results of the AWG’s “current policy scenario” projections for spending on pensions, health and long-term care using the per capita GDP costs rule completed in 2001, with the projections for public expenditure on education and unemployment benefits completed in 2003. Pension spending forecasts for Austria, France, Germany, Spain and Portugal take into account the effects of the recent pension reforms and the revised population projections.

3.2 From expenditure projections to sustainability analysis. – The expenditure projections provided by the AWG are used for building up sustainability indicators, which provide a quantitative estimate of the budgetary adjustments required for a Member State to ensure sustainable public finances and compliance with the SGP. The starting point is given either by the general government today accounts or by forecast accounts for the last period considered in the Stability and Convergence programmes. The initial non-pension primary expenditure and revenue are kept constant over time while the pension expenditure developments are projected on the basis of a set of assumptions on demographics, labour participation rates and other relevant variables. Given certain assumptions concerning GDP growth and interest rates, the increase in the spending ratio is used to project the primary balance and the debt dynamics.

These computations are then used for building up tax gaps (also called “sustainability gaps”), i.e. the difference between the current tax ratio and the constant ratio that would be needed over the projection period to achieve a pre-determined budgetary target at a specified date in the future (for correcting the projected values which take into account the pension-expenditure projections). Since the choice of both the targeted debt ratio and the length of the projection period is arbitrary, the European Commission calculates two different tax gaps, covering a range of definitions of sustainability used in the literature:
The adjustment required to reach the same debt level in 2050 that would result from a balanced budget position over the entire projection period;

• the adjustment that would guarantee the respect of the inter-temporal budget constraint of the government. In this case there is no target for the debt level, which will converge towards a relatively low level. 28

These indicators are calculated for two scenarios: the programme scenario and “current year” scenario, where the starting point is the current budget position. The latter scenario demonstrates the long-term impact on debt developments, and consequently on the sustainability of public finances, of a failure to achieve the ‘close to balance or in surplus’ requirement of the SGP for those countries still in deficit.

As for the future, the EPC has a mandate to deliver a new set of common budgetary projections by mid-2005 for all 25 EU countries. A number of guiding principles for the design and execution of the projection exercise has been agreed upon in order for the AWG to fulfil this ambitious mandate: i) an appropriate balance between the need for simplicity and the economic relevance has to be found in choosing the methodology to be used to forecast age-related public expenditure items; ii) in order to ensure comparability, adjustments for individual country specific circumstances should be kept to a minimum with the principle of equal treatment for all countries being respected; iii) the assumptions underlying the expenditure projections should be consistent with each other; iv) the assumptions underlying the projections should be adopted on a prudent basis; v) all key inputs and assumptions should be clearly specified, along with the projection models.

The coming exercise aims at providing policy makers with a better assessment of the sources of risks to public finances in the long-run. The exercise will involve sensitivity tests. Where possible, probabilities will be attached to alternative scenarios. To this end, the following steps have been agreed by the AWG.

• Projections will extend to 2070, so as to cover the working lives of all people alive today.

• The new projections will be based on a revised set of Eurostat population projections. Appropriate sensitivity tests for different scenarios on population developments will be carried out.

• The age-related expenditure projections will continue to be performed using national models and agreed, but more tightly specified, assumptions on key economic parameters.

• The same underlying assumptions on economic parameters (participation and employment rates, productivity growth, real interest rates) will be used in all the projection exercises.

• National authorities will report projection results in a common reporting format to be developed by the Commission.

The AWG plans to produce policy simulations regarding migration, 29 pension reforms, health care and long-term care, labour market developments and the Lisbon employment targets.

3.3 Problems with EU pension projections. – The joint projections exercises carried out by the AWG represent an important step forward. First, they make sure that all EU countries regularly produce pension expenditure projections. Second, the need to update the projections regularly, to discuss them in a multinational context and to respect some agreed guidelines provides an incentive to produce unbiased

28 There is no cut-off date, which and this requires the assumption that age-related expenditures remain constant as a ratio to GDP at the projected level in 2050.

29 The simulations would assess the contribution of inward migration flows to offsetting some of the economic and budgetary implications of ageing populations.
forecasts. Third, the common demographic and economic assumptions increase the comparability of outcomes.

However, there are still a number of problems. Differences in modelling approaches, coverage of projections and the significant margin left to national authorities to fix underlying economic assumptions make the results not strictly comparable. The information made public is often not sufficient for a full assessment of the forecasting exercises and for conducting alternative exercises. Moreover, the institutions assigned to make the projections are often those responsible for designing social policy, which may affect both the availability and the substance of the forecasts and of the available information.

4. The role of pension liabilities

This section explores the potential role of PAYG pension liabilities in the EU fiscal framework. A radical solution would imply assimilating pension liabilities to conventional public debt. This would also require a change in the computation of the budget balance: social contributions would be considered as loans to public pension schemes and pension spending as loan repayments.

The proposals to estimate pension liabilities and to use them in the assessment of fiscal sustainability are part of a broader tendency to extend the analysis of fiscal sustainability from the conventional public debt to a more comprehensive and forward-looking concept of public liabilities. Some studies develop a comprehensive measure of the government balance sheet; others develop synthetic indicators of the fiscal adjustment required to put or maintain the government’s financial position on a sustainable footing in the long-term; other studies assess the distribution of the burden of fiscal commitments across different generations (Box 4). These approaches share the advantage of providing synthetic indications about the overall situation of public finances or about their long-term prospects. But they also share some shortcomings that suggest some caution in their policy use.

Box 4

The government balance sheet approach and the synthetic indicators of fiscal sustainability

The government balance sheet. – In recent years some studies have pointed to the deficiencies of conventional cash-flow deficit measures in the assessment of fiscal impact and of budgetary sustainability. They have argued that the level and the changes of conventional public debt do not provide comprehensive indications about the sustainability of the fiscal position. In order to overcome these difficulties it has been prescribed to resort to “economic deficit” or to “government net worth” (Kotlikoff, 1984, Buiter, 1983. For a critique see Mackenzie, 1989; for a survey see Towe, 1991, and Blejer and Cheasty, 1991). These solutions would require to consider public assets and all explicit or implicit liabilities. In particular, all “contingent liabilities” should be estimated. These liabilities may emerge from the government commitment to provide services or transfers and from its involvement in the economy (guarantees of the debt of public enterprises or of deposit insurance).

Synthetic indicators. – The development of synthetic indicators of fiscal sustainability is closely related to that of long-term projections. Blanchard (1985) and Buiter (1985) aim at evaluating the amount of sustained fiscal adjustment required to balance the present value of the long-term budget constraint. Both authors assume that a government should be able to pay back new debts through the accumulation over time of net surpluses, i.e. any anticipated future deficit must be offset by surpluses at some point in time. A forward-looking perspective is taken by the tax-gap indicator
proposed by Blanchard et al. (1990). This gives a measure of the adjustment in the taxes-to-GDP ratio required today and to be sustained until some terminal point in the future to allow the debt ratio to return to its initial value. Delbecque and Bogaert (1994) estimate the “recommended primary surplus”, which is defined as the primary surplus that would guarantee the long-term sustainability of fiscal policy, given the existing pension expenditure projections. It allows pension expenditure increases to be fully offset by a decline in interest payments caused by a fast reduction in the debt-to-GDP ratio. Similarly, Chand and Jaeger (1996), evaluates the tax adjustment required to cover the anticipated shortfall in receipts relative to pension liabilities examining the unfunded pension liabilities of several industrial countries. Frederiksen (2001) estimates the changes in the primary balances that would allow some OECD countries to achieve fiscal sustainability.

Synthetic indicators provide summary information about the need for fiscal adjustments and about intergenerational trade-offs. For instance, they allow the evaluation of the impact of increases in taxation on current generations on the burden carried by future generations. Their value derives from the simplicity and the policy symbolism (Heller, 2003). However, they are aggregate measures that do not provide any information about the pattern of surpluses or deficits that would emerge in different periods or of the likely economic consequences of any particular time path. They are also subject to the same weaknesses and deficiencies of the long-term projections on which they are based. In particular, they are sensitive to assumptions about expenditure trends. As long-term projections, synthetic indicators do not give any insight about the probability that measures taken to close a specified gap will result in a fiscally sustainable solution. Furthermore, results are contingent on the underlying assumptions on parameters such as the starting budget position and interest and growth rates. They can also be significantly affected by the choice of the terminal point of the exercise.

Generational accounting. – Generational accounting estimate the burden that present tax and transfer policies imply for future generations and the fiscal adjustment required for ensuring that future generations face the same burden of current generations (Auerbach et al., 1991, Auerbach, 1992; for a review of estimates see Raffelhüschen, 1997, and Leibfritz, 2000; for a critical assessment see Buiter, 1985, and Haveman, 1994). Generational accounts are based on the net public debt that must be serviced in the future, on projections of demographic developments and on projections of future government spending. Future generations are assumed to pay the debt not paid out by current generations. Age-related expenditure profiles and household composition are usually assumed to remain constant. The estimates require assumptions about the allocation across generations of the benefits of the non age-related government purchases of goods and services.

In the generational accounting framework, government policies are assumed to induce no change in economic behaviour so that the relative estimates are deterministic and lack any endogeneity. Estimates depend very much on to the starting levels of deficit and debt and economic and demographic assumptions. Being based on long-term projections of budgetary items, these accounts suffer from the problems associated with forecasts. The estimation of public expenditure attributed to each age group is problematic. The estimation of present net worth value is also difficult. The comparability of the results obtained for different countries may be limited if the expenditure profiles are estimated with reference to different age groups, budgetary items and definitions of public sector. From a policy point of view, much as in the case of the tax-gap, it is also relevant that the synthetic indicators derived from generational accounts do not provide information about the timing of the effects of demographic changes. Moreover, its results are not intuitive, which may hamper their use for policy objectives, and are very sensitive to assumptions about the determination of private consumption, productivity growth and discount rates (see Hagemann and John, 1995, and IMF, 1996).
4.1 How to define pension liabilities. – Any PAYG pension scheme gives rise to unfunded liabilities. Within these schemes each generation provides the resources for paying the pensions to the previous generation and later receives pensions financed by younger workers. Therefore, at any point in time there exist a number of retired citizens who are entitled to a pension for the remaining part of their life (and sometimes also of the life of their widowed spouse) and a number of working citizens who can claim a right to a pension either in the near or in the distant future.

There exist three main definitions of pension liabilities (Castellino, 1985; see also Box 5).

1. **Accrued-to-date liabilities**: these represent the present value of pensions to be paid in the future on the basis of accrued rights; neither the future contributions of existing workers, nor the accrual of new rights by them are considered.

2. **Current workers and pensioners’ net liabilities**: it is assumed that pension schemes continue their “existence until the last contributor dies, while no new entrants are allowed”; both the future contributions of existing members and their new rights are therefore allowed for under current rules.

3. **Open-system net liabilities**: these also include the present value of contributions and pensions of new workers under current rules; the range of options extends from including only children not yet in the labour force to an infinite perspective.

The three pension liabilities definitions share the pensioners’ liabilities component, but differ as to the workers’ component. More specifically, the first definition includes only the present value of accrued-to-date benefits of present workers. The second one also refers to the future benefits of present workers and to their future contributions. The last definition also considers the benefits and contributions of people who have not yet entered the labour market.

---

**Box 5**

**The valuation of pension liabilities**

This box formalises in an extremely simplified way the key equations for representing the three pension liabilities definitions reported above. Disability pensions and survivor pension are not accounted for. It has to be noted that the equations which follow should be considered as applying to each single pension scheme existing in a country, since pension schemes usually have different features and rules (regarding age, sex, wage, contributory periods, etc.). The differentiation of rules for males and females is also not considered.

**The valuation of accrued-to-date liabilities.** – Accrued-to-date liabilities ($L$) represent the present value of pensions to be paid in the future on the basis of accrued rights. They include both present pensioners’ liabilities ($LP$) and present workers ones ($LW$).

In principle, the pension liabilities pertaining to each pensioner of age $a$ are as follows:

---

30 A PAYG pension scheme is “a pension finance arrangement whereby current liabilities are met from current contributions, and no fund is accumulated in advance to meet future needs” (Dilnot et al. 1994, p. 212). The debt arises with the creation of the PAYG pension scheme, when a generation of elderly citizens receives a pension without having paid any previous contribution or when the contributions do not guarantee an adequate pension.

32 This definition corresponds to the concept of “net social security wealth” developed by Feldstein (1974) and frequently referred to in the debate concerning the effects of social security on saving decisions.
\[ L_P = \sum_{i=0}^{\infty} \frac{B_i S_i}{(1 + r)^{i-a}} \]

where \( B_i \) represents his pension in year \( i \), \( S_i \) represents his probability to be alive in year \( i \), \( r \) is the discount rate. By assuming that the pension increases at a constant rate \( (p) \) and given the pensioner’s present pension \( (B_d) \) one obtains:

\[ L_P = B_d \sum_{i=0}^{\infty} \left( \frac{1 + p}{1 + r} \right)^{i-a} \]

The total present value of pensions existing in year \( t \) is the following:

\[ L_P(t) = \sum_{j=2}^{\infty} N^p_j B^p_j \sum_{i=t}^{\infty} S^p_{i,j} \left( \frac{1 + p}{1 + r} \right)^{i-t} \]

where \( j \) is the minimum pension age, \( N^p_j \) is the number of pensions paid to pensioners of age \( j \) in year \( t \), \( B_j \) is the average pension paid to pensioners of age \( j \) in year \( t \) and \( S^p_{i,j} \) is the probability to be alive in year \( i \) for pensioners of age \( j \) in year \( t \).

Along the same lines, the present value of workers’ liabilities \( (LW) \) can be computed.

\[ LW1(t) = \sum_{j=2}^{\infty} N^w_j \left[ B^w_j \sum_{i=t}^{\infty} Q_{i,j} S^w_{i,j} \left( \frac{1 + p}{1 + r} \right)^{i-t} \right] \]

where \( N^w_j \) is the number of workers of age \( j \) in year \( t \), \( B^w_j \) is the average pension paid at retirement to workers of age \( j \) in year \( t \) computed on the basis of contributions already paid, \( Q_{i,j} \) is the probability of receiving a pension at in year \( i \) for workers of age \( j \) in year \( t \), \( S^w_{i,j} \) is the probability to be alive in year \( i \) for a worker of age \( j \) in year \( t \).

**The valuation of current workers and pensioners’ net liabilities.** – These represent accrued-to-date liabilities of workers and pensioners plus the present value of the rights present workers will acquire in the future net of future contributions of present workers.

While accrued pensioners liabilities are as before, the workers component also takes into account the present value of the rights that present workers will acquire in the future (WFB, workers’ future benefits) net of the future contributions of present workers (WFC, workers’ future contributions):

\[ LW2(t) = LW1(t) + WFB(t) - WFC(t) = \]

\[ = LW1(t) + \sum_{j=2}^{\infty} N^w_j \left[ B^w_j \sum_{i=t}^{\infty} Q_{i,j} S^w_{i,j} \left( \frac{1 + p}{1 + r} \right)^{i-t} - C \sum_{i=t}^{\infty} R_{i,j} Y_{i,j} \left( \frac{1 + p}{1 + r} \right)^{i-t} \right] \]

where \( B^w_j \) is the average pension paid at retirement to workers of age \( j \) in year \( t \) computed on the basis of contributions to be paid in the future, \( C \) is the contributory rate on labour income, \( R_{i,j} \) is the probability of working in year \( i \) for workers of age \( j \) in year \( t \) and \( Y_{i,j} \) is the labour income in year \( i \) of a worker of age \( j \) in year \( t \).

**The valuation of open-system net liabilities.** – These include the present value of accrued and future rights of present workers and pensioners and the present value of pensions of new workers net of the present value of their future contributions.

While accrued pensioners’ liabilities and the net liabilities concerning present workers is as in the second definition of liabilities, one has also to consider the present value of the pensions of new workers (FWB, future workers’ benefits) net of the present value of their future contributions (FWC, future workers’ contributions). In case only children living at \( t \) are considered:

\[ LWN(t) = FWB(t) - FWC(t) = \sum_{j=1}^{7} N^C_j \left[ B^C_j \sum_{i=t}^{\infty} V_{i,j} S^C_{i,j} \left( \frac{1 + p}{1 + r} \right)^{i-t} - C \sum_{i=t}^{\infty} K_{i,j} Y_{i,j} \left( \frac{1 + p}{1 + r} \right)^{i-t} \right] \]
where $N_{ij}$ is the number of children of age $j$ in year $t$, $B_{ij}$ is the average pension paid at retirement to children of age $j$ in year $t$ computed on the basis of full working life, $V_{ij}$ is the probability of receiving a pension at time $t$ for children of age $j$ in year $t$, $S_{ij}$ is the probability to be alive in year $i$ for a children of age $j$ in year $t$, $C^*$ is the contributory rate on labour income, $K_{ij}$ is the probability of working in year $i$ for children of age $j$ in year $t$, $Y_{ij}$ is the labour income in year $i$ of a children of age $j$ in year $t$ and $\bar{j}$ is the age at which individuals enter the labour force.

So overall (actual and future) workers’ liabilities under this definition are as follows:

$$\text{LW3}(t) = \text{LW2}(t) + \text{LWN}(t) = \text{LW1}(t) + [\text{WFB}(t) - \text{WFC}(t)] + [\text{FWB}(t) - \text{FWC}(t)]$$

In other words, the last two definitions differ from the first one because they account also for new expected net rights (of a closed and of an open system, respectively). Therefore, these indicators can play a role in the assessment of the perspectives of pension schemes. Moreover, as new net pension rights can be estimated for different generations of born and unborn citizens, they can be useful in assessing the role of the public sector in determining the distribution of resources.

Estimates of pension liabilities require detailed information about the specific pension rules of each country and about the features of workers and pensioners with respect to age, sex, wage and contributory periods. These estimates depend on several assumptions on mortality rates, activity rates, wage and price trends. The discount rate of future contributions and benefits play also a crucial role. In addition, the last two definitions of pension liabilities require an assessment of the expected value of future contributions.33 In countries where pensions are included in the personal income tax base, liabilities should be net of the presumed taxes levied on them.34 This requires an estimate of the average tax rate on pensions. In this regard, it has to be considered that even assuming the stability of the present income tax rate structure in real terms,35 the average tax rate on pensions may change over time since the ratio of pension to other income may change. In countries where public pension schemes are fully or partially funded, liabilities should be computed net of pension fund assets.

4.2 Accrued liabilities. – Among the three definitions of pension liabilities, that of accrued-to-date liabilities is the only one that can be assimilated to conventional public debt.

Present pensioners and workers’ liabilities and open-system liabilities include pension rights that are yet to accrue. Strictly speaking, these pension rights should not even be called liabilities but potential liabilities. They cannot therefore be assimilated to conventional public debt, which is a backward looking statistic.

This section examines the indications provided by accrued liabilities and their possible role in the EU fiscal framework.

33 In the case of public pension schemes, this may raise some methodological problems. In some countries current pensions are fully financed by specific contributions to pension schemes. Future contributions can thus be assessed on the basis of present contribution rates. In other countries current pensions are also financed via other sources, such as general tax revenues and borrowing. In this latter case, if future contributions are assessed on the basis of the contribution rate to pension schemes, there is a tendency to overestimate liabilities. The overestimation would be particularly large for the countries relying mostly on general taxation. If, on the other hand, the relevant contributory ratio is assumed equal to the pension-to-expenditure ratio in the base year, there is a tendency to underestimate the imbalances of countries relying on borrowing. It would be better to try to assess future contributions on the basis of the present contributory rate to pension schemes plus present recourse to general taxation. In other words, present recourse to borrowing should be excluded from estimates of future contributions. However, also this method would involve some arbitrary assumptions.

34 No such adjustment is necessary for conventional public debt, since no tax is levied on public bonds when they are refunded.

35 Tax rates are adjusted to income changes in order to keep the tax to income ratio constant.
Accrued liabilities and the sustainability of PAYG schemes. – The information that pension liabilities provide can be better understood by considering two stylised cases: the first one takes a macro perspective (see infra); the second one takes a micro perspective and highlights the effects of demographic changes (see Box 6, where also a numerical example is considered).

Let us consider a steady state situation where the ratio of any expenditure to GDP is constant over time. Suppose there are two countries (A and B) in which, ceteris paribus, PAYG pension spending is respectively $X$ and $aX$ per cent of GDP (where $a>1$). Overall public spending is the same in both countries because country A devotes $(a-1)X$ per cent of GDP more spending than country B to non-pension spending programmes. Country A and country B devote on a permanent basis revenues amounting respectively to $X$ and $aX$ of GDP to their PAYG schemes. In the steady state, the ratio of accrued-to-date liabilities to GDP is given by the discounted value of the ratios of future pension spending to GDP and so the latter is proportional to pension spending as a share of GDP. This means that, notwithstanding the same underlying sustainability circumstances, country B pension liabilities are $a$ times those of country A.

Therefore, the size of unfunded pension liabilities does not indicate that PAYG systems are unbalanced or will be unbalanced in the future. The matter should be rather judged in terms of the efficiency of PAYG schemes and their role in achieving society’s equity objectives.

Overall, both the examples which consider the economy from the macro perspective and Box 6 makes it clear that the ratio of accrued pension liabilities to GDP is not a measure of pension schemes sustainability or, more generally, of public finances sustainability. The size of the liabilities depends on the decision concerning the benefits and eligibility criteria of PAYG schemes, but it does not provide any information on whether the PAYG system is unbalanced or will be unbalanced in the future. A high liabilities-to-GDP ratio does not necessarily imply an imbalance in the PAYG pension schemes or in the budget. Nor does it imply that an imbalance will occur in the future.

Any judgement about the sustainability of pension schemes requires estimates about the resources available to pay for the accrued pensions, namely about the evolution of employment and per capita income. Accrued-to-date liabilities do not include such estimates. All one can say is that the larger the ratio of pension rights to GDP, the higher the share of future public resources committed to pension expenditure and the higher the risk that, if GDP growth is not adequate, some adjustment will become necessary (in terms of higher tax rates, of repudiation of pension rights, etc.). Some pension schemes include mechanisms that automatically adjust contributions or benefits to the new developments.

It can also be argued that a country relying only on PAYG schemes can be in a worse position than a country relying on both PAYG and funded schemes in terms of risk differentiation and the absorption of shocks. However, neither theory nor experience support the view that the recourse to PAYG schemes rather than to funded schemes necessarily implies less sound public finances.\(^{36}\)

On the other hand, accrued rights measure the cost of closing down a PAYG scheme when fully complying with present rules concerning benefits:\(^{37}\) if there is a switch from a PAYG system to a funded system and all new contributions are paid into the new system, accrued rights measure the amount of resources which have to be financed out of general taxation.

---

\(^{36}\) The PAYG versus funding argument is very complex and is beyond the scope of this paper. See, for instance, the papers in OECD (1992) and Sartor (1993).

\(^{37}\) See World Bank (1994).
Pension liabilities and sustainability: is there a link?

We consider a very simplified economy in the steady state with a constant population structure. We show that the ratios to GDP of both accrued liabilities and pension expenditure are constant over time. As long as the contributory rate is higher than the expenditure ratio this system is sustainable.

We then introduce a demographic shock in the system. The shock will be such that the ratio of liabilities to GDP will be the same as before, but the expenditure ratio will increase over time till above the contributory rate. Therefore, the shock will lead the system to be unbalanced.

This means that, for a given ratio of accrued-to-date liabilities to GDP, a country can be on either a sustainable or an unsustainable path.

The steady state. – Assume that the interest rate is equal to the rate of growth of the amount paid to each pensioner (which is constant so that discounting cancels out). Moreover, assume that pensions accrue at a constant rate during working years (each worker accrues a fraction of the pension \( p \) which is inversely proportional to the expected length of the retirement period). GDP is given by the sum of workers’ product (which coincides with their wage \( w \)).

The timing in such an economy is as follows: individuals do not work until they reach a certain age \( WA \) (working age), then they work till they reach age \( RA \) (retirement age) and they benefit from a pension till they reach age \( DA \) (death age). This timing is the same for every individual. Population does not grow over time: the birth rate and the death rate are the same so that the number of pensioners and that of workers are both constant over time.

The ratio of accrued-to-date pension liabilities to GDP at time \( t \) is as follows (see Box 5 and take into account the simplifying assumptions mentioned above):

\[
\frac{L(t)}{Y(t)} = \frac{LP(t) + LW(t)}{Y(t)} = \frac{\sum_{a=RA}^{DA} N_a^p (DA - a) p + \sum_{b=WA}^{RA} N_b^w (b - WA)(DA - RA) p}{N^w w} = \frac{p \left( \sum_{a=RA}^{DA} N_a^p (DA - a) + \sum_{b=WA}^{RA} N_b^w (b - WA)(DA - RA) \right)}{N^w w}
\]

This means that the ratio of accrued-to-date pension liabilities to GDP at time \( t \) is given by the ratio of the average per capita benefit to the average per capita wage (which is also the average per capita GDP) times the ratio to the number of workers of the sum of the number of pensioners, weighted for their life expectancy, and the number of workers, weighted for their expected life as pensioners times their share of working life already worked. Given the assumptions on the demographic developments of this economy this ratio is constant over time and depends on the decision concerning the retirement age. The higher \( RA \) is, the smaller the pension liabilities are.

In this context also the pensions expenditure-to-GDP ratio is constant:

\[
\frac{P(t)}{Y(t)} = \frac{P}{Y} = \frac{\text{pension expenditure}}{\text{GDP}} = \frac{N^p w}{N^w w} = \frac{N^p p}{N^w w}
\]

As long as the ratio of pension expenditure to GDP is less than or equal to the contributory rate \( c \) (constant), the system is balanced.
If we compare pension liabilities to pension expenditure, we get:

\[
L/Y = \frac{p \left( \sum_{a=RA}^{DA} N^p_a (DA - a) + \sum_{b=WA}^{RA} N^w_b \frac{(b - WA)}{(RA - WA)} (DA - RA) \right)}{\text{w}}
\]

\[
P/Y = \frac{p \frac{N^p}{w}}{N^w}
\]

\[
= \frac{\sum_{a=RA}^{DA} N^p_a (DA - a) + \sum_{b=WA}^{RA} N^w_b \frac{(b - WA)}{(RA - WA)} (DA - RA)}{N^p}
\]

Therefore, the ratio between liabilities and pension expenditure does not depend on either the average pension or the average wage. It depends on the ratio to the number of pensioners of the sum of the number of pensioners, weighted for their life expectancy, and the number of workers, weighted for their expected life as pensioners times their share of working life already worked. Basically, for any given \(p/w\), the ratio depends on the structure of population.

**The shock.** – Suppose that a “demographic shock” occurs: there are more workers than in the steady state (the baby-boom generation enters the labour force). Assume that this increase in the workforce does not change the ratio of accrued-to-date liabilities to GDP. This is possible as long as the new workers imply a proportional increase in accrued liabilities and in overall gross domestic product. If the demographic shock implies an increase in the number of just-entered workers (i.e. an increase in the number of workers of age \(WA + 1\)) then, given that in the steady state the number of workers of age \(WA + 1\) was \(N_{WA+1}^w\), after the shock the number of workers of age \(WA + 1\) is \(N'_{WA+1}\) where \(N'_{WA+1} = \alpha N_{WA+1}\) and \(\alpha > 1\). Therefore, after the shock the ratio of accrued liabilities to GDP can be written as follows:

\[
L(s) = \frac{L + (\alpha - 1)N_{WA+1}}{Y(s)} \frac{(DA - RA)}{(RA - WA)} p
\]

where \(s\) refers to the period when the shock occurs and \(L\) and \(Y\) are the steady state values of liabilities and GDP, respectively. Therefore, if:

\[
\begin{cases}
(\alpha - 1)N_{WA+1} (DA - RA) (RA - WA) p = kL \\
(\alpha - 1)N_{WA+1} w = kY
\end{cases}
\]

where \(k\) is a positive constant, then the increase in the workforce leaves the ratio of accrued liabilities to GDP unchanged. Obviously there is an infinite number of \(k\) values for which the system is satisfied. Moreover, the system is satisfied (i.e. the demographic shock can leave the liabilities-to-GDP ratio unchanged) as long as the ratio of the retirement period to the working period, weighted by the ratio of the average pension to the average wage, is equal to that of the steady state liability-to-GDP ratio:

\[
\frac{p (DA - RA)}{w (RA - WA)} = \frac{L}{Y}
\]

In the shock-period the system is still balanced. Indeed, the pension expenditure ratio to GDP is lower than in the steady state (the number of pensioners is the same as before while GDP is higher) while the contributory rate is as before.

Nevertheless over time, as the baby-boom generation retires (i.e. at time \(s + [RA - (WA + 1)]\), the system will be unbalanced. Indeed at that time, while GDP will return to the steady state value, the pension expenditure will be higher than in the steady state (i.e. \(N^p_{SS} + (\alpha - 1)N^w_{SS+1} p\), where \(N^p_{SS}\) is the pensioners number in the steady state and
$(\alpha - 1)N_s^{WA+1}$ is the number of baby-boom pensioners, i.e. the additional workers as compared to the steady state which were in the labour force at the time the shock occurred. As $c$ is not likely to be high enough, the system will be unbalanced, i.e. the pension expenditure to GDP ratio will exceed the contributory rate:

$$\frac{P(s + [RA-(WA+1)])}{Y(s + [RA-(WA+1)])} = \frac{[N^p + (\alpha - 1)N_s^{WA+1}]p}{N^w} > c$$

Therefore, the ratio of accrued liabilities to GDP does not imply anything in terms of sustainability: the steady state economy and the after-shock economy share the same liability-to-GDP ratio but completely different perspectives in terms of sustainability of the pension system.

**A numerical example.** – Suppose we have a steady state economy with the following population structure. There are four citizens: one is 10 years old, one is 30, one is 50, and one is 70. Assume that every citizen works from age 20 to age 60 so that the second and the third citizens work; their gross income is €100 each. The oldest citizen is retired; his pension is €40. Suppose GDP is the sum of workers’ product (€200). The contributory rate on workers’ income, which corresponds to the ratio of pension expenditure on GDP, is 20 per cent. Assume that incomes and pensions grow at a constant rate and that this rate is equal to the interest rate. Also assume that pensions accrue at a constant rate during working years (with a present value of €1 per year) and that everyone lives 80 years.

The retired citizen accrued rights amount at €400 (€40 times 10 years of expected life); the two workers’ accrued rights amount to €800 (€10 times 20 years of expected life in retirement for the first worker and €30 times 20 years for the second worker). Altogether, pension liabilities amount to 6 times GDP. As the contributory rate is set to remain stable at 20 per cent and the ratio of pension expenditure to GDP is not going to exceed 20 per cent over time, the system is balanced.

Now, suppose that there is a demographic shock: the baby boom generation enters the labour market so that the economy is as before, but there are two more people. More specifically, workers aged 50 are now three. Pension liabilities and GDP are, respectively, €2,400 (€30 times 20 years of expected life in retirement times two in addition to the previous €1,200) and €400 (since there are four workers); the ratio between the two is, as in the steady state, equal to 6. Pension expenditure is presently 10 per cent of GDP but in 10-years time it will rise to 60 per cent and become unsustainable, given the 20 per cent contributory rate.

Therefore, the steady state economy and the post-shock economy share the same accrued-to-date liabilities (which are 6 times GDP) but they are very different in terms of sustainability, i.e. perspective pension developments which depend on their demographic structure.

**Accrued liabilities and public debt.** – With reference to accrued-to-date liabilities, it can be argued that “from the worker’s point of view, social security “tax” contributions are, in most respects, equivalent to the purchase of a government liability” (Kotlikoff, 1984; p. 567). In fact, an abrupt end to or a radical change in a PAYG scheme would impose large adjustment costs and personal hardships to pensioners and workers who have taken their savings and labour supply decisions on the basis of the existence of the scheme. Nevertheless, accrued pension rights differ in many ways from conventional public debt (see also Rizzo, 1985, Pedone, 1987 and Bohn, 1992).

---

38 In many countries pensions are indexed to price dynamics. Therefore, the assumption that relates them to wage dynamics tends to overestimate pension expenditure. On the other hand, in many countries there are rules that work the opposite way. For instance, pensions are frequently based on the wages earned in the latter part of working life, which are often higher than the average real wage earned during the whole life.

39 According to Bohn (1992, p. 4), “One should distinguish between a social-security system in its start-up phase, where the first generation of participants receive substantial "unearned" benefits, and a more mature system. Since promises to make gifts are generally unenforceable, the benefits promised in the start-up phase cannot be considered government liabilities. On the other hand, it is difficult to imagine that a government could cancel the social-security benefits of retirees who have made social security contributions throughout their life”. This distinction, although appealing, is not easily applied.
First of all, while the timing of the repayment of public bonds as well as the amount to be paid to the holders are fixed in advance, those of pension liabilities are uncertain. Indeed, they depend on decisions made by the holders of the entitlements (concerning, for instance, the age of retirement, where some flexibility is allowed) and on various types of events (those concerning the length of life, wage and price dynamics, etc.).

Second, pension rights are not embodied in formal contracts. The debtor can modify both the timing and the amount of the payment. While failure to repay financial liabilities may give rise to legal claims and political reactions, the repudiation of PAYG pension liabilities may raise only the latter. Pension liabilities can be reduced by changing benefit rules: major pension reforms have reduced the future entitlements of current workers and pensioners. Indexation mechanisms, retirement ages, eligibility rules and other aspects of the pension system have been frequently modified in recent years in developed countries. Consequently, it would be erroneous to assume that pension programs represent a firm legal or moral commitment.

Moreover, while public bonds are usually bought freely on the market by individuals or companies, the acquisition of pension rights is usually compulsory. This means that a large pension-debt does not determine any direct pressure on the financial markets. It also implies that the debt is automatically renewed.

Finally, pension rights are not tradable. This implies that changes in the relative yield and the relative risk of pension rights comparatively to other assets have no effect on financial markets. It also implies less protection for pension-right holders than for bond holders. Bohn (1992, p. 45) notes that: “For government debt, any attempt to default – outright or through inflation – would imply undesirable market disruptions. Such “protection” against default does not exist for social-security claims. In addition, non tradability implies that social-security claims could be altered selectively, taking individual characteristics into account.”

**Accrued-to-date pension liabilities and fiscal policy assessment with reference to EU debt.** – The previous Sub-section has pointed to the differences between accrued pension liabilities and public debt. In the EU framework the inclusion of pension liabilities in the public debt definition would raise additional problems.

First, conventional public debt can be measured rather precisely and unambiguously at any point in time. Pension liabilities are uncertain and depend on the specific assumptions adopted upon a variety of factors, such as life expectancy, price and wage trends. Present value calculations are extremely sensitive to changes in assumptions. This is particularly problematic in a context where figures are to be provided for twenty-five countries.

---

41 The elasticity of pensions to price and wage changes is frequently different from 1.
42 On the political-economy of support to pension expenditure see Buchanan (1983), Rizzo (1985) and Tabellini (1990).
43 The Italian pension reform of 1992 provides a clear case: 30 per cent of the pension-debt was wiped out at a time when public finances were considered to be in a very critical situation.
44 One should nevertheless consider that the implementation of large cuts in pension rights may obviously raise political reactions and that these reactions are likely to increase with the gradual shift of political power towards the older generations. As Börsh-Supan (1991, pp. 129-130) notes: “In West Germany after 2020 the majority of the voters will be pensioners and workers who will become retired within the next 10 years. We then risk facing a typical free-rider situation as the older generation can outvote the younger generation in determining their retirement income as well as the rate of social security taxes the younger generation has to pay.”
45 A large future pension expenditure may obviously influence the attitude towards public bonds, but this is an indirect effect.
46 As Boskin *et al.* (1987, p. 45) point out, referring to the USA: “Moving all of the economic and demographic projections from intermediate to either optimistic or pessimistic (assumptions) results in a change which is larger than the privately held national debt.” The effects on deficit estimates would even be relatively larger.
Second, as pension rights are acquired compulsorily and are not tradable, they produce no direct effect on financial markets. The inclusion of pension liabilities in the debt and deficit measures would obscure the pressure of the public sector on financial markets.\(^{47}\)

Third, the inclusion of pension liabilities in the public debt definition would either require an analogous change in the deficit definition or enlarge the degree of incoherence between the two indicators European fiscal rules refer to. Let us consider the first case. Currently, contributions are recorded as government revenue and pensions as payments to retirees. The change would imply that contributions are classified as loans to the public sector, which would not be taken into account in computing the deficit indicator (Oksanen, 2004). Pensions would be considered as loan repayment. In this accounting system, an increase in contribution rates would, \textit{ceteris paribus}, have no effect on either current or future deficits.\(^ {48}\) Any increase in the benefits promised for the future would increase current deficit and leave future ones unchanged. These changes would blur any indication concerning the impact of the fiscal policies of each country on the area fiscal stance. Although pension liabilities surely affect consumption and saving decisions,\(^ {49}\) the magnitude of the impact is not necessarily equal to that of public financial liabilities. Pension rights holders may have limited foresight, may not trust present or future government's capacity to deliver the full pensions they are entitled to under present rules, may be cash-constrained, may live in a world with imperfect capital markets. The inclusion of pension rights in debt and deficit statistics on a one-to-one basis might lead, therefore, to an erroneous estimate of the impact of fiscal policy.\(^ {50}\)

Fourth, the addition of pension liabilities to the conventional public debt would produce misleading indications of the effects of changes in interest rates on public expenditure perspectives and budgetary sustainability. Since accrued pension liabilities are negatively related to the level of the interest rate, any increase in this level would automatically reduce total debt. This development can look like an improvement, however it might correspond to an actual worsening of budgetary conditions due to the increase in interest expenditure.

Fifth, the inclusion of pension liabilities in debt and deficit statistics would obviously influence international comparisons of public finance data. The amount of the total public debt would depend on the structure of the pension system. More specifically, the countries relying on PAYG schemes would record a higher debt than those relying on funding. However, one can wonder why pension expenditure should be treated differently as compared to other types of expenditure. In most countries citizens are entitled to receive medical care, education and other services. It may be debatable to what extent the government is legally obliged to meet such potential obligations. It can be argued that to some extent all spending programmes create implicit contracts containing future liabilities (Heller, 2003).\(^ {51}\)

\(^{47}\) The case of Italy may again be relevant. Despite the fact that the 1992 reform wiped out pension liabilities equal to Italian conventional debt, the role of the public sector in the financial markets has not changed significantly.

\(^{48}\) It has also been suggested that part of the repayment be considered an implicit interest payment. Kotlikoff (1984) supports this solution. Towe (1991, p. 117) notes that “proponents of this system do not address the issue of decomposing benefit payments into “principal” and “interest”. Presumably, actuarial criteria could be applied.” In this case, the impact of changes in current contribution rates would depend on the link between contributions and benefits.

\(^{49}\) As to savings, see for instance Rossi and Visco (1994) who suggest that the growth of PAYG schemes’ liabilities contributed substantially to the decline in Italian saving ratio between the 1960s and the 1980s.

\(^{50}\) This point is extensively examined in Mackenzie (1989).

\(^{51}\) On this point, Brittan (1993) takes a radical view: “The fallacy of such estimates (of pension liabilities) is to treat pension commitments differently from other forms of public spending. The PAYG schemes, from which the scare stories stem, are based on each generation of workers paying through taxes and contributions sufficient to cover the cost of pensions for those already retired. Thus, pensions are, like any other form of rising public expenditure, to be met from higher tax revenue or social security contributions, or reduced spending elsewhere.” Penner (1982, p. 234) notes that: “One might argue that the degree of political commitment to future pensions is somewhat stronger than to other entitlements in that pension benefits
Finally, the inclusion of pension liabilities in the public debt definition, by making citizens’ entitlements more explicit, may hamper the implementation of the pension reforms needed to ensure fiscal sustainability in several European countries.52

4.3 New net liabilities and the sustainability of PAYG schemes. – Present pensioners and workers’ liabilities and open-system liabilities include net pension rights that are yet to accrue. Strictly speaking, these pension rights should not even be called liabilities but potential liabilities. They cannot therefore be in any way assimilated to conventional public debt, which is a backward looking indicator.

As already mentioned, new expected rights may play a role in the assessment of the perspectives of pension schemes. Future rights are positive when the discounted flow of benefits is higher than the discounted flow of contributions; they are negative when the former flow is smaller than the latter. We now turn to the possible economic and sustainability implications of positive and negative net future rights.

In a “pure” PAYG system, in any period, the total amount of pensions paid out is given by the total amount of contributions:

\[ p \cdot N^P = c \cdot w \cdot N^w \]

where \( p \) is the average pension, \( N^P \) represents the number of pensioners, \( c \) is the contribution rate levied on wages, \( w \) is the average wage and \( N^w \) represents the number of workers.

If \( c \) is constant over time, \( w \), \( N^P \) and \( N^w \) dynamics are exogenous and \( p \) is adjusted in each period of time in order to balance expenditures with revenues (i.e. there is a “pure” PAYG system), it can be shown that the rate of return on contributions \( (rc) \) is approximately equal to the sum of the rates of growth of per capita wages \( (\dot{w}) \) and of the number of workers \( (\dot{n}_w) \).53

\[ rc = \dot{w} + \dot{n}_w \]

To grasp the intuition underlying this result, think of a two-period economy. In the first period individuals work and pay contributions. In the second period individuals get a pension. Overall, pension expenditure in each period is equal to the contributions paid in the same period by the generation which is currently working. Pensioners get a pension which depends on the number of working individuals and on the wage of those individuals. Therefore, the return on the contributions paid in the previous period by today’s pensioners depends on the growth rate of the number of workers and on the growth rate of wages.

A “pure” PAYG pension policy is sustainable, in the sense that it does not require any change in rules, as long as \( rc = \dot{w} + \dot{n}_w \).

52 Boskin (1982) notes that: “I would not wish to have the current rules and regulations of the social insurance program cemented into a unified capital account of the government as if we had issued explicit long-term contractual debt obligations, that is, I do not want to enshrine pay-as-you-go financing of these programs and government activities at current projected levels.”

53 See Aaron (1966).
In practice, most PAYG systems are not “pure” systems, i.e. \( p \) is not adjusted in each period of time in order to balance expenditures with revenues. In other words, \( rc \) is not necessarily equal to \( w + nw \).

Net pension rights are positive if the implicit return on contribution is greater than the return rate assumed as a benchmark (i.e. if \( rc > r \)) but the sign of net pension rights does not convey any information on whether or not there is an imbalance in the PAYG scheme. The amount of pension rights does not provide any information on whether the rate of return on contributions is either larger or smaller then the sum of the rate of growth of per capita wages and of the rate of growth of the number of workers which is the relevant aspect in assessing the need to modify pension policy.

The sign and the dimension of pension rights crucially depend on the choice of \( r \), which is rather arbitrary. If \( r \) is very high, even a scheme where \( rc \) is much higher than \( w + nw \) would show negative net rights. Conversely, if \( r \) is very low, even a scheme where \( rc \) is much lower than \( w + nw \) would show positive net rights.

In conclusion, positive net rights do not imply that the pension system is presently unbalanced in cash terms or that it will become unbalanced within a certain time. Neither do they imply that some adjustment will have to take place in the future. On the other hand, there may exist circumstances in which even with null or negative new expected rights the pension system can exert large cash pressure on the budget.

It would be more relevant to provide estimates of \( rc \) and to compare them with present and future values of \( w + nw \) (this is precisely the indication provided by the equilibrium contributory rate). Unless one assumes that a certain rate of return on contributions represents a normative benchmark for the assessment of PAYG schemes, any comparison between \( rc \) and an arbitrary \( r \) does not lead very far.

Had estimates of new net rights been carried out in the 1960s and the 1970s, they would have probably shown large positive values because \( rc \) was in many countries higher than it is now. The large positive values would have implicitly signalled that citizens were granted very high returns on contributions and that these returns were unlikely to be continuously matched by a high level of \( w + nw \). The availability and the diffusion of estimates might have limited the tendency to improve pension benefits and might have accelerated the reform of pension schemes. Recent estimates, that take the reforms of the 1980s and the 1990s into account, are apparently less worrying. Van den Noord and Herd (1993) record negative or nearly null new net rights in four out of the seven countries that they consider. In spite of that, due to the decline in \( w + nw \), the situation of pension systems is very worrying: a declining number of new workers is being called to service a large accrued debt.

In a way, estimates of future net rights were not available when they were mostly needed. Now that they are available, it is apparent that in many countries the problem does not lie in avoiding that future net rights have positive values but in cutting accrued rights and in getting new generations of workers to accept negative net rights.

5. Estimates of pension liabilities

Estimates of pension liabilities are subject to measurement errors and to misinterpretation, as the projections for pension expenditure. They are based on specific assumptions concerning a variety of factors, such as future labour force participation rates, retirement behaviour, unemployment, prices and earnings. As for
demographic calculations, forecasts rely on techniques for projecting future pension payments from available data on current and past trends. Estimates can be based on administrative data concerning the work history of individuals or on panel data tracking the economic activity of successive cohorts of individuals.

The first international comparisons of pension liabilities were provided in 1989 by Hagemann and Nicoletti and in 1993 by Van den Noord and Herd and by Kuné et al. The first and the second papers were prepared within the OECD. The third was prepared within ABP (Algemeen Burgerlijk Pensioenfonds - the pension fund of the Dutch public employees), for the CEPS Working Party on “Financing Retirement Provision in Europe”.

Hagemann and Nicoletti (1989) refer to pension scheme accounts in 1985; the other authors refer to 1990 accounts. The countries considered do not coincide. Only Germany is analysed in all three papers. Before examining the data, however, it is necessary to consider some methodological issues.

The studies are based on a highly simplified methodology. In Van den Noord and Herd (1993), for each country a “full pension” (which is actually an average pension) is computed dividing total public expenditure on pensions by the number of beneficiaries. The present value of current benefits is estimated on the basis of the full pension, of mortality rates and of a discount rate. Pensions are supposed to be held constant in real terms. The paper shows that estimated pension liabilities on average are about twice as large as conventional debt; future pension rights are projected to generate liabilities amounting to 3.5 times GDP, almost twice as much as the level of liabilities associated with existing entitlements. Furthermore, countries with high debt-to-GDP ratio also tend to have high pension liabilities-to-GDP ratio.

In estimating the pension rights of current workers, Van den Noord and Herd (1993) assume that in each country the standard retirement age is sixty, and the number of years of contributions required for a full pension is forty. They also assume that pension entitlements accrue at a constant rate of 1/8 of the full pension every five-contribution years. Present workers are grouped in eight five-year brackets. The members of each bracket are assumed to be entitled to the same pension rights. During working life, pension entitlements are projected to grow at the same rate as projected real earnings and real output per worker. This means that the ratio of the average new pension to real earnings per worker is held constant. An exception is made for Canada and the United Kingdom “where pension rates undergo a structural upgrading”.

Kuné et al. (1993) follow broadly the same lines. Standard retirement age is nevertheless assumed to be sixty-five, and no structural upgrading is considered. In Van den Noord and Herd (1993) the different PAYG schemes existing in each country are considered as a single “average” system; in Kuné et al. (1993) the present value of pension rights is estimated separately for public sector and private sector workers.

In Van den Noord and Herd (1993) the discount rate is 4 per cent in real terms in the period 1990-2010; after that, it gradually declines reaching 3 per cent in 2050. An alternative projection with a discount rate 1.5 per cent higher than in the baseline is also presented. In Hagemann and Nicoletti (1989) the discount rate is set at 2 per cent for Germany, Sweden and the US and at 3.5 per cent for Japan. In Kuné et al. (1993) the discount rate is 4 per cent for the whole projection period.

In all the papers some assumptions are clearly unsatisfactory.

- In many countries younger pensioners, who obviously are expected to live longer, on average receive higher pensions than older ones. The assumption that the pension level is uniform tends to underestimate 54

---

54 The first and the second papers were prepared within the OECD. The third was prepared within ABP (Algemeen Burgerlijk Pensioenfonds - the pension fund of the Dutch public employees), for the CEPS Working Party on “Financing Retirement Provision in Europe”.

55 That is for a pension equal to the 1990 average pension.

56 Structural upgrading may depend on younger generations of citizens retiring with longer contributory periods or with more favourable rules concerning the determination of the pension paid.
the present value of current pensioners’ rights. Besides, the use of the current average pension as the term of reference for the level of future pensions may lead to erroneous estimates. Estimates may turn out too low if pension levels undergo a structural upgrading, or too high if rules concerning the level of new pensions have been tightened.

- In some countries (like Germany and Italy up to 1992) pensions are also indexed to real wages. Holding pensions constant in real terms determines an underestimate of liabilities.57
- Hagemann and Nicoletti (1989) and Van den Noord and Herd (1993) do not provide separate estimates for public and private sector workers. This may lead to some underestimation of liabilities since in many countries in the last decades public employment has grown faster than total employment and public employees usually have better retirement rules.
- Kuné et al. (1993) do not take into account that some pension systems may not yet have reached maturity (i.e., that the ratio of average new pensions to average earnings may increase over time). Hagemann and Nicoletti (1989) consider structural upgrading for Japan and Sweden. Van den Noord and Herd (1993) consider it for Canada and the UK.58

Table 2 presents the estimates of accrued pension liabilities according to Van den Noord and Herd (1993) and Kuné et al. (1993). The data concerning the four major EU Member States show that estimates vary considerably: the UK’s liability ranges between 42 and 139 per cent of GDP, France’s between 69 and 216. Van den Noord and Herd (1993) provide the highest estimates and Kuné et al. (1993) the lowest. The ranking of the four countries is very different: Germany comes first according to Kuné et al. (1993) and third according to Van den Noord and Herd (1993).

Furthermore, in the estimates by Van den Noord and Herd (1993), pensioners’ rights represent 30 to 40 per cent of total rights. In the estimates by Kuné et al. (1993), civil servants’ rights represent 40 per cent of total pension rights in Belgium, France and Germany. It is a much higher percentage than their incidence in the labour force. This supports the view that pension liabilities ought to be estimated separately for all the major schemes with different rules existing in any country.

---

57 Van den Noord and Herd (1993) provide an estimate of the pension liabilities of the seven major western countries under the assumption that all pension benefits after retirement are indexed to earnings. Accrued pension liabilities are 10 to 20 per cent higher than in the case of price indexation.

58 As regards Italy, for instance, only one third of the increase in the ratio of public pension expenditure to GDP between 1960 and 1990 may be attributed to demographic changes (Franco, 1993). The increase in the pension-to-GDP ratio that was forecast before the 1992 pension reform was also largely attributed to the maturation of pension schemes.

** Figures in brackets are estimates of liabilities before the 1992 pension reform.

Table 3 shows some estimates of current workers and pensioners’ net liabilities and open-system net liabilities. It should be noted that Kuné et al. (1993) do not take into account the future flow of contributions to PAYG schemes. This tends to overestimate pension liabilities. Van den Noord and Herd (1993) assume that in five of the seven countries considered, contributions to PAYG schemes are going to be equal, with respect to GDP, to the incidence of their expenditure on GDP in 1990. This means that no part of 1990 public budget deficits is attributed to public pension schemes. It follows an underestimation of future liabilities of pension schemes. For the two remaining countries, contributions are computed at present rates. The latter methodology is also applied by Hagemann and Nicoletti (1989).

59 The countries are Canada, France, Germany, Italy and the United Kingdom.
60 As to the USA, legislated future increases contribution rates are taken into account.

* Percent of 1985 GDP. Swedish liabilities are estimated as 183 or 228 percent of GDP according to pension indexation to prices or to wages.
** Data for Canada and the UK have been updated as in Van den Noord-Herd (1993).
*** Figures in brackets are estimates of liabilities before the 1992 pension reform.

Van den Noord and Herd (1993) provide estimates regarding present workers, children not yet in the workforce and unborn citizens. According to the paper, “A positive number in such an account implies a net debt of the government to a specific generation, and hence a net transfer of wealth to that generation.

63 OECD (1993, p. 54).
Similarly, a negative number represents a net debt of a particular generation to the government and hence a net transfer of wealth to that generation”.63

According to these estimates, in Canada and Japan rights for new generations are accruing faster than contributions. Some adjustment to contribution rates or benefit rules would therefore be necessary in order to avoid new transfers of resources to pensioners. In France and Germany “accruals of contributions would broadly match new accruals of pension rights (while leaving the existing accruals unfinanced)”64 In Italy, the United Kingdom and the United States future generations have already “been called to transfer wealth to current generations”. This does not imply that in the latter countries there is scope for improving benefits or for cutting contribution rates.

Hagemann and Nicoletti (1989) provides an estimate of the unfunded pension liabilities of all individuals aged between seventeen and ninety years in 1985. Its results should be comparable with the sum of Van den Noord and Herd (1993) accrued rights and new net rights of the present workforce. Again, the estimates differ very much: 355 per cent of GDP in Hagemann and Nicoletti (1989) as against 149 per cent in Van den Noord and Herd (1993) for Germany, 158 per cent as against 91 per cent for the USA, 217 per cent as against 173 per cent for Japan (Table 3). A part of the difference surely depends on the assumptions about the discount rate. In the case of Germany it may also depend on the different methodologies used in estimating future contributions.

The different solutions adopted by Van den Noord and Herd (1993) and Kuné et al. (1993) for evaluating future contributions also explain the different results in Table 2 and Table 3.

Table 4 reports the results of some estimates of pension liabilities carried out at national level in more analytical terms.65 UK and Italian estimates are rather larger than those presented in Tables 2 and 3.66 In the case of Italy there is a huge difference between the estimates of liabilities existing before the 1992 pension reform and those relative to the effects of the reform. Van den Noord and Herd (1993) results concerning Italy, which also contrast with those of other studies concerning the perspectives of the Italian pension system,67 depend largely on the overestimation of future contribution and on the underestimation of benefits arising from the assumption considered above.

National studies show that in some countries the ratio of pension liabilities to GDP has grown considerably during the last decades; accordingly, in these countries, economic deficits have been much larger than conventional cash flow deficits. The inclusion of the change in liabilities in deficit statistics would have increased the Italian deficit by 11 points of GDP every year between 1971 and 1981 and by 5 points every year between 1981 and 1991.

Chand and Jaeger (1996) estimate discounted net pension liabilities, defined as current accrued rights of pensioners and workers plus the prospective liabilities that will be accumulated in the future. Furthermore, the paper estimates the primary balance required to finance these projected pension liabilities (Table 5). According to the paper, net pension liabilities range from 5 per cent of GDP for the United Kingdom to about 110 per cent of GDP for France, Germany and Japan. The authors add these liabilities to the net public debt

64 But this would not matter as long as the PAYG systems were not terminated.
65 Some papers providing estimates for Argentina, Chile, China, Colombia and Turkey are indicated in World Bank (1994).
66 The gross liabilities of Italian pension schemes have been estimated also in Pench (1993), which discounts the flow of expected pension expenditure up to the year 2025. The paper aims at evaluating the permanent (seignorage-adjusted) primary surplus excluding pensions required to ensure fiscal policy sustainability; for that reason it does not deduct future contributions from future expenditure.
and argue that if “one judges the sustainability of a nation’s fiscal stance in terms of the conventional criterion of stabilising net public debt at its current levels, it would appear that the present fiscal stance of Italy and Germany are sustainable: their projected primary balances in 1995 exceed the amounts needed to stabilise the ratio of net public debt (excluding pension liabilities) to GDP”.

Disney (2001) criticises the methodology adopted by Chand and Jaeger because they put together calculations on an accrual basis (column 1) with projections (column 2) and cash flows (column 3). The projected net liabilities incorporate future flows of contributions that will generate further liabilities. Moreover, instead of solving for the equilibrium PAYG contribution rate required to finance future expenditures, the rate is arbitrarily fixed at its current level, which may not be sustainable. This generates an arbitrary net pension liability, which is then added to an existing one (net public debt). Finally, the “sustainable” primary balance is summed up to a cash flow measure (the current budget balance) to generate a fiscal adjustment. On the contrary, Disney suggests a different method consisting in starting with the net public debt and add to it a net pension liability based on accrued pension liabilities to date and then find the primary balance required to service such a resulting debt.

Source: Chand and Jaeger (1996).

(B) Net present value of the difference between projected primary expenditure and revenue of public pension funds during 1995-2050, adjusted for net asset position of public pension systems at the end of 1994.

Frederiksen (2001) aims at estimating the immediate and permanent adjustment of the primary surplus required to forestall the need for further future changes of fiscal policy. He follows two approaches. The first one consists in a comparison between the actual pattern of fiscal consolidation (basically, the actual structural deficit) and the required pattern of consolidation. The latter reflects the need to offset the projected future decrease in the primary surplus due to greater age related spending, as estimated by the AWG.

In the second approach, Frederiksen compares the actual structural primary surplus with the “required” primary surplus. The latter is measured estimating the interest burden both on the explicit net debt and on the implicit debt reflecting the future budgetary consequences of current legislation. In 2000, in the nineteen countries considered the ratio of government net explicit liabilities to GDP amounted on average to 46 per cent. The implicit liabilities amounted to 194 per cent of GDP. This means that the “official” net debt amounted to only one-fifth of the effective debt burden.

In principle, the two approaches should give the same results to the extent that the assumed constant interest rate is a good proxy of the return on current government financial assets and liabilities. The average

---

68 The main assumptions are a nominal GDP growth rate of 4 per cent and a nominal rate of interest equal to 6 per cent. Consequently, the growth-adjusted rate of return is 2 per cent.
improvement of the primary balance required for the nineteen countries is actually the same (2.3 per cent of GDP) but there are some significant differences at the country level.

Frederiksen (2001) reports the changes in the pension expenditure-to-GDP ratio and the total amount of implicit liabilities (which are based on the open system methodology). The relative position of most countries remains the same either when countries are ranked on the basis of the changes in ratio of pension expenditure to GDP or on the basis of implicit liabilities. The countries with highest expenditure growth are those with the greatest liabilities. Exceptions are represented by Australia, Denmark, Germany, the Netherlands, Portugal and Sweden (Table 6).

On the contrary, the ranking of countries in terms of the current spending levels (see OECD, 2001) does not correspond to their ranking in terms of implicit liabilities. One can expect that countries with the highest pension expenditure-to-GDP ratios have the greatest accrued liabilities, but they do not necessarily have the greatest open system liabilities.

This survey clearly indicates that there is considerable uncertainty concerning the size of pension liabilities and that different definitions of liabilities point to very different assessments of country positions.

6. Expenditure projections versus liabilities

Expenditure projections and liabilities provide different indications concerning the future of pension schemes. Expenditure projections are a flow concept. They do not require any discounting but they must be compared with a relevant denominator. Liabilities are a stock concept. They are computed by discounting future flows.

Expenditure projections and liabilities refer to different future flows. In terms of the definition developed in Section 4, expenditure projections imply taking into account (a) all the accrued liabilities of pensioners and workers, (b) the gross liabilities of current workers (i.e. the gross value of the workers’ component of the second definition of liabilities) and (c) the gross liabilities of perspective workers (i.e. the gross value of the perspective workers’ component of the third definition of liabilities).

Source: calculations based on Frederiksen (2001).
The following Figure qualitatively depicts the relationship between pension expenditure projections and the various definitions of pension liabilities, where liabilities are defined as in Box 5 (accrued-to-date liabilities are given by \( LP(t) + LW1(t) \); future gross benefits of current and perspective workers are \( WFB(t) \) and \( FWB(t) \), respectively). In particular, at a given point in time (time A) accrued-to date liabilities are going to die out as the last pensioner exits the system; later on workers’ future benefits will start to decline while, in the case of open systems, liabilities will keep growing.

**Pension Expenditure Projections and Pension Liabilities**

![Diagram showing the relationship between pension expenditure and liabilities](image)

To better understand the relationship between pension liabilities and pension expenditure it would be advisable to distinguish between expenditure components, i.e. between expenditure relating to accrued liabilities, to future liabilities of current workers and to future liabilities of perspective workers. The composition of pension expenditure projections can provide information on the feasibility of pension reforms: the larger the accrued component the less likely reforms are and, if implemented, less likely reforms are to be effective (as they are likely to deal with the not-yet-accrued-component).

In addition, it could also be worthwhile to compute not only expenditure projections but also liabilities projections, especially with reference to the accrued-to-date definition. Indeed, the stability of such projections can indicate that the system is not likely to run into problems. The opposite holds, if such projections are on an increasing path.

Consequently, it would be advisable to have information concerning all the three liabilities’ definitions as they provide different types of hints.

The use of expenditure projections or of the different definition of pension liabilities depends on the issue to be examined.
6.1 Evaluating the overall impact of ageing. – Although pension schemes are likely to exert the greatest strains on developed countries’ budgets in the next few decades, a wider approach is required in the assessment of the effects of ageing. Population ageing will actually influence most expenditure items in both directions. On one hand, it will increase health care expenditure since the consumption of services raises steeply with age and it will also increase the demand for some social services. On the other hand, the decline in the number of young people will provide an opportunity to reduce education expenditure and the decline in total population growth and, in some countries, the decline of total population, may reduce the requirements for capital expenditure.

Fiscal sustainability should be assessed with an accounting framework that considers all budgetary items.69 Pension expenditure projections can be easily combined with projections for other budgetary items. On the contrary, referring to liabilities rather than to spending would be problematic with reference to health, long-term care, welfare and education outlays.

Moreover, netting out of earmarked contributions is not relevant when assessing the overall sustainability of fiscal policy. It discriminates against systems which finance pension expenditure not only via contributions but also via general taxation.70

6.2 Evaluating the sustainability of pension schemes. – The pension expenditure-to-GDP ratio and the contribution rate that assure the cash balance of pension schemes give straightforward indications concerning sustainability. On the other hand, neither the size of accrued liabilities nor those of present pensioners’ and workers’ liabilities and open system liabilities indicate whether the schemes are sustainable (see Section 4).

Moreover, age-related expenditure projections can provide more intuitive indications than liabilities measures and are less sensitive to underlying assumptions. Small changes in starting conditions and assumptions can determine large shifts of pension liabilities (EPC, 2003). Moreover, as all liabilities’ measures are stock measures based on present value calculations they share the drawback of being highly sensitive to changes in the discount rate. Moving to flow variables can allow to get rid of this problem.

However, liability measures can provide other types of information. Accrued liabilities indicate the cost of closing the scheme. Open-system liabilities, which include new net expected pension rights, provide a measure of the difference between the implicit return on contributions to PAYG schemes and some rate of return assumed as a benchmark. Estimates of new net rights do not provide any measure of present and future cash imbalances, nor do they provide information on the need to adjust contribution rates or benefit rules, or on pressures on the budget.

6.3 Trading future reforms with higher current deficits. – Within the European debate on the effectiveness of the SGP, several proposals to render fiscal soundness and structural reforms compatible have been put forward. In November 2002 the European Commission stressed that, for countries which have already made

70 The CBO (2004) stresses that “the term “unfunded liability” has been used to refer to a gap between the government’s projected financial commitment under a particular program and the revenues that are expected to be available to fund that commitment. But no government obligation can be truly considered “unfunded” because of the US government’s sovereign power to tax – which is the ultimate resource to meet its obligations.”
substantial progress towards the achievement of the medium-term target set by the SGP, a small and temporary deterioration in the underlying budget position could be envisaged in the face of structural reforms.

Applying this idea to pension reforms means “trading” a temporary worsening in today’s fiscal balance for a reduction in future deficit and debt via a reform of the pension system: once a country had put structural reforms into effect, the medium-term target would be modified accordingly.

Suppose that a country is allowed to worsen its deficit at time $t$ in the face of commitments to reduce its debt below a certain threshold by time $t+T$ via a pension reform. The assessment of this “trade” could be dealt with in two ways.

First, as each period debt is the previous period debt plus current deficit, one can estimate the reduction in pension expenditure due to the reform and, consequently, the corresponding improvement in future deficits and then the new debt development path which guarantees a certain debt level at time $t+T$.

Alternatively, one can estimate the change in future liabilities due to the reform (i.e. the discounted flow of changes in pension spending). Nevertheless, this second solution is not easy to deal with, as it is not straightforward to assess the relationship between deficit, conventional debt and pension liabilities. Therefore, referring to pension expenditure rather than to pension liabilities seems more intuitive and easier to implement.

6.4 Evaluating the impact of pension wealth. – Pension liabilities can be more effectively used to evaluate the fiscal impact on consumption and saving ratios, of deficits in accrual terms, and of the economic balance of pension schemes.

As present pensioners’ and workers’ liabilities basically correspond to social security wealth, they are relevant for the assessment of fiscal effects on saving decisions. Furthermore, they highlight the future cost of present pension policies and they may reduce the incentive “for fiscal authorities to substitute away from cash to non-cash activities as a means of circumventing constraints on the overall cash-based deficit or expenditure”.

7. Further progress is needed

A broad assessment of fiscal sustainability in EU countries requires complementing the current deficit and debt indicators with forward-looking indicators. In this context, estimates of the impact of the pension system on the budget are necessary. This can be achieved either via projections of future pension spending or via estimates of pension liabilities. In the previous Section we have examined the different properties of the two types of indicators and have argued that the use of expenditure projections or of the different definition of pension liabilities depends on the issue to be examined. We have also underlined that pension expenditure projections seem the most appropriate tool for sustainability analysis.

As noted in Section 3, the availability and quality of pension expenditure projections in the EU have greatly improved but there remain significant problems, which hampers their use in assessing fiscal sustainability. In particular, projection comparability among EU countries is still unsatisfactory. Furthermore, progress is still required in the organisation of projections and in their technical features both at the national and at the EU level.

Improvements in the quality of pension expenditure projections would also enhance the quality of estimates of pension liabilities.

7.1 Organisation aspects. – In a rapidly changing demographic context, where reforms of social policies continue to be politically problematic, more attention needs to be paid to the way in which projections are organised, in particular to the attribution of responsibilities, to the accountability requirements and to the frequency and transparency of the exercises. The availability of accurate long-term projections is a necessary condition for the efficient design of social policy.

Projections indicating a significant increase in future spending necessarily trigger discussion of reform. By contrast, the lack of projections can allow reforms to be avoided or deferred. In the end, only if public opinion has sufficient awareness of future long-term obligations will reform be politically practicable (Boeri et al., 2000).

In light of the greater role that long-term sustainability is going to play in the EU fiscal framework, in principle the most appropriate solution would be to assign the responsibility for pension expenditure and pension liabilities estimates to a unique institution at the EU level. This solution, which would ensure the comparability of national projections, raises two problems. First, it would require that all EU countries agree on a common method and accept a certain loss of sovereignty. Second, on a more technical ground, a unified forecasting authority and a common method may imply losses in terms of details and quality of projections. This problem can be dealt with only if a close link is established between the new institution and the national authorities in order to allow the former to benefit of the expertise of the latter.

An alternative solution would be that of retaining the current responsibility of national institutions while strengthening the coordination concerning the organisation of projections. This is the approach followed so far at the EU level. Tighter common guidelines and greater peer pressure would increase comparability and transparency. A step in this direction is envisaged for the 2005 projection exercise of the AWG. However, additional efforts need to be made in eliminating differences in coverage, models and techniques. Adjustments for individual country specific circumstances should be kept to a minimum. Allowed differences should be explained in detail and motivated.

The following general points apply to both organisational scenarios.

Responsibility and accountability for the exercises. – Both expenditure projections and pension liability estimates should be detached from policy considerations and from country specific interests. The agencies assigned to produce forecasts should not be those responsible for fiscal and social policy. Ideally, forecasts should be assigned to a technical agency that reports directly to Parliament.

An alternative solution would be the coexistence of a number of different public and private forecasting institutions. In this case, no monopoly on data should be allowed and the costs of running forecasting models
should be lowered. This could be achieved by requiring the public agencies that hold data to make them promptly available to all interested parties. Forecasting models developed in the public sector should be made available to all possible users.

**Frequency of projections.** – Forecasts should be made on a regular basis (for instance every two or three years), not in connection with political evaluation of the effects of specific reforms. This would enhance the credibility of projections.

**Transparency.** – Repetition of forecasting exercises inevitably means the revision of previous results. This may be due to changes in the demographic and economic framework or to changes in the model. Every exercise should have a detailed discussion of the reasons for the revision. This enhances transparency and heightens the incentive for accurate projections.

The results of the projections should be released in the form of analytical papers that allow for an assessment of the underlying assumptions; they should include tests of sensitivity to demographic, economic and behavioural variables. The reports should provide detailed information about different indicators. For instance, in the case of pension expenditure, both the ratio of outlays to GDP and the equilibrium contribution rate should be provided. There should be detailed projections on the number of pensioners and the size of the average pension, broken down by type of pension and category of worker. In a system in which public pensions also give income support to unemployed in working age, the preparation of consolidated accounts of social spending by age-groups would help to isolate and evaluate the functions actually performed by the pension system. Estimates of pension liabilities should also be provided, in particular concerning accrued liabilities.

**7.2 Technical aspects.** – The quality of pension expenditure projections has greatly improved in recent years. However, further progress is required in a number of areas.

**Coverage.** – Projections, as well as estimates of liabilities, should cover all pension schemes. In order to evaluate the overall effects of ageing, projections should cover also the other age-related public expenditure items, such as health, long-term care and education. In addition, one should aim at projecting also the remaining expenditure items and revenue, in order to allow an assessment of the overall sustainability of public finances.

**Methodology.** – Projections should be based on demographic scenarios prepared, for the sake of comparability, by Eurostat with the involvement of national statistical institutes. They should cover a period sufficiently long (at least fifty years) to let the size and age structure of the population to converge towards a new equilibrium level and to allow all people currently in the labour force to retire. However, projections should also consider the non-demographic factors affecting pension spending, such as the composition of the workforce and the retirement decisions of individuals.

---

72 Fornero (1997) suggests running the models “backwards” to see whether, using the actual values of the demographic and economic variables, they accurately “predict” spending.

73 Additional efforts should be made in modelling public spending on health and long-term care taking into account also non-demographic factors (past expenditure trends, “death-related” costs, the degree of institutionalised provision of long-term care and the change in the health care status of older people).
Dealing with uncertainty. – Forecasting models are generally deterministic and the assumptions concerning demographic and economic variables are often based on their own past performance. This mainly reflects the difficulty of handling models that must consider many economic, demographic and behavioural factors and yet produce results quite quickly. Estimates are generally based on scenario analysis.74 The issue of evaluating uncertainty can be tackled in different ways. One can associate probabilities to forecast ranges stemming from alternative scenarios.75 One can also use stochastic simulations assigning a probability to an arbitrarily large sample of input combinations, solve for the system’s finances under each set of paths and then use the probability associated with each set of inputs to create a probability distribution for the outputs.76

Data. – It is important that the data on which projections are based are frequently and regularly updated and promptly made available to forecasters. In particular, given the rapid evolution of family structures, the probabilities of the main family events need regular revisions. For instance, it would be useful to have a protocol whereby the institutions supplying the data needed for forecasting pledge to release them regularly.

Underlying assumptions. – Every forecast is based on a large number of assumptions concerning demographic trends, economic variables and individual behaviour. It is obviously important that the projection reports make these assumptions explicit and describe their margin of uncertainty. Moreover, the reports should consider whether the simplifying assumptions ordinarily used in all projections are effectively justified. In age-related expenditure forecasts, for example, there should be greater attention to analysis of the main demographic and behavioural variables by cohort, to avoid simplistic assumptions producing unrealistic spending forecasts.77 In particular, one would need a careful evaluation of the estimates of survival for the very old (over eighty), since it has been observed that those now available tend to overestimate mortality (Caselli, 1996, and National Research Council, 2001). The assumptions concerning family events (marriage, age and status of survivors, etc.) and individuals’ behavioural choices need to be set out in detail. It would be helpful to have a breakdown by age, sex and year of forecast, of assumptions on the retirement probability of individuals in the retirement age bracket.

Labour market. – The level of pension spending depends on the evolution of the labour market. The equilibrium contribution rate critically depends on it. The key factors are the participation rates of older

74 This is only a first step towards a determination of the uncertainty in the estimates since projections do not usually incorporate any overall measures of probability for the input scenarios and therefore it is not possible to evaluate the likelihood of the results. This approach allows evaluating how results would be affected if all the values for inputs moved in the same direction even though remaining plausible. The high and low estimates serve as boundaries.
75 See Technical Panel on Assumptions and Methods (1999).
76 In stochastic models, inputs take values based on random variables and final forecasts result from the application of Monte Carlo simulations (Meyerson and Sabelhouse, 2000; CBO, 2003). A stochastic approach solves some of the problems set out above but may complicate the forecasting process. It requires simulating several demographic processes for each year in the forecast concerning e.g. births, deaths, marriages, divorces and immigration. This may require developing a model for each of these processes and relate them with one another or develop a unique model containing all details at the cost of a higher simplification of reality.
77 In order to limit the gap between forecasts and outcomes, Lacasse (1994), Reynauld and Vidal (1994) and Strobel (1994) stress the importance of a correct identification of potential beneficiaries of the social programmes and of the study of their behaviour, since individuals may change their behaviour in order to be entitled to social benefits.
workers and of women. Spending forecasts should be based on studies concerning, for instance, the incentives to retire provided by social security rules, workers’ retirement choices and the present and future health conditions of elderly citizens. Forecasts should be able to use data on career histories, earnings and marital status of individuals. The need to consider the retirement behaviour of individuals is accentuated by the tendency to allow individuals to freely decide their retirement age within a certain age bracket.

**Living standards.** – Projections should provide the information needed to evaluate the overall standard of living of the elderly. In particular, they should specify the size of public pensions paid to various groups of citizens according to age, sex, place of residence and family status. The data on public pensions should be supplemented by those on private pension plans and other incomes to produce an assessment of the overall economic situation of retirees. Obviously, public pension programmes interact with public action in other areas of social protection. A reduction in public retirement provisions not offset by an increase in other incomes could trigger stronger demand for action and also for certain types of health care services. Only if these aspects are taken into account can one truly judge the social sustainability of social security rules or reforms. Studies of the overall economic situation of retirees, which requires microsimulation models, could be performed less frequently than spending projections and could be assigned to different agencies.

8. Conclusions

A growing concern about the sustainability of pension systems, health-expenditure growth and rising welfare spending have urged many governments to produce long-term projections (Heller, 2003). In the last two decades, the latter have assumed an important role in the fiscal policy debate and in the formulation of public policy.

The paper has examined the main developments at the national and EU level and has pointed to the three main trends characterising the European scene as regards the long-term analysis of public budgets:

- the rapid spread of projection exercises to all countries and a tendency to conduct them on a regular basis, not contingent on reform proposals;
- the increasingly close linkage of the analysis of pension spending to the sustainability of public finances as a whole;

---

78 The importance of this is underscored in OECD (1995a and 1995b) and is made plain in the exercises conducted for Economic Policy Committee (2000) with reference to the “Lisbon Scenario”. See also European Commission (2000b) and Visco (2001).

79 This will require the formation of data banks which follow the evolution of various cohorts over time. On this, see National Research Council (2001). Jimeno (2000) notes that without data on the employment and earnings history of individuals it is hard to evaluate the effects of reforms.

80 Peracchi et al. (2001) emphasise the importance of longitudinal surveys providing demographic and economic information.

81 For a study along these lines see Sartor (2001), who gives estimates of the equilibrium contribution rate for private sector employees and of the average pension for different age cohorts. Sartor uses sample data and relates the results for the pension system to a generational accounting exercise.

82 This is taken into consideration in OECD (1999).
• the awareness that trends in pension spending, through their impact on the budget balance, have repercussions at the EU level and, hence, that there is a need for internationally comparable projections and for systematic monitoring of spending in each country.

In the current debate on the European fiscal rules there is a widespread consensus on the need to place more focus on government debt and long-term fiscal sustainability in the surveillance of budgetary positions. The way to make this operational has not yet been defined. The paper has examined the possible use of pension expenditure projections and estimates of pension liabilities.

The paper has noted that sustainability issues should be primarily addressed by considering the projections concerning the pension expenditure-to-GDP ratio and the contribution rate that assures the cash balance of pension schemes. While acknowledging the rapid progress in the availability and quality of projections, the paper has noted that the organisation, comparability and quality of projections still present several limitations. The national institutions responsible for the projections are often those responsible for designing social policy, which may affect both the availability and the substance of the forecasts. National projections are produced with different models and coverage is not homogeneous. The information made public is often not sufficient for an adequate assessment of the forecasting exercises and for conducting alternative exercises. Further efforts should therefore be devoted to pension projections both at the national and the EU level before they can be attributed an operational use in the EU fiscal rule framework. An appropriate measurement at the EU level would require not only common assumptions, but also common forecasting procedures and coverage. This requires further integration among national forecasting institutions.

Concerning pension liabilities, the paper has argued that pension liabilities may bring a clearer understanding of the impact of fiscal policies, may provide a measure of the cost of terminating pay-as-you-go pension schemes and may be useful for the measurement of deficits computed on an accrual basis. However, the level of pension liabilities does not provide indications concerning the sustainability of pension schemes and their effects on public budgets. The assessment of the sustainability of pension systems and the pressure of pension schemes on the budgets should primarily refer to expenditure to GDP ratios and equilibrium contributory rates. Pension liabilities should not be added to conventional debt.

The paper has argued that both pension expenditure projections and estimates of pension liabilities can usefully complement the deficit and debt indicators currently used in the EU fiscal rules. In addition, it has stressed that it is necessary to improve some technical and organisational aspects concerning age-related expenditure projections, such as the independence of forecasters, the transparency of projections and the homogeneity of methods. Improvements in the quality of pension expenditure projections would also enhance the quality of estimates of pension liabilities.

Franco, Marino, and Zorreri focus on pension liabilities, which largely determine the sustainability of public pensions and affect long-term fiscal positions. They discuss this issue with special reference to the fiscal consolidation among EU countries under the Stability and Growth Pact (SGP). After examining the pension expenditure projections available in EU countries and their use in the assessment of fiscal sustainability, they discuss the different definitions of pension liabilities and their potential role in the EU fiscal framework. They argue that the level of pension liabilities cannot provide any indication about the sustainability of pension schemes, but that estimates of pension liabilities can complement the deficit and debt indicators currently used. They also point out some technical and organizational issues concerning projections.

This paper gives us a clear understanding of how we should consider pension liabilities in the context of public pension reforms. Although the analysis of the paper is much oriented to the EU fiscal policy discussions, it contains various policy implications to other industrialized countries including Japan. First of all, their examination about the three definitions of pension liabilities – (1) accrued-to-date liabilities, (2) current workers and pensioner’s net liabilities, and (3) open-system net liabilities – is of great help in understanding pension liabilities and avoiding any confusion.

Regarding their assessment of pension liabilities, let me make two comments. First is on their argument that the level of pension liabilities is not a good indicator of the sustainability. It makes sense. To compare the levels across countries is irrelevant in many cases, and it seems to be a crucial point for assessing EU fiscal consolidation under the SGP. However, we can analyze pension liabilities in a dynamic framework; for example, growing net pension liabilities over time can be interpreted as a warning signal of rising unsustainability of the system. As mentioned in section 6, regular monitoring of the time-series evolution should be useful in gauging the sustainability.

The second comment is on the implications of pension liabilities to the overall fiscal policy and intergenerational equity. Among their three definitions, open-system net liabilities, which are the most comprehensive one, give important information in this respect. For example, positive open-system net liabilities would mean that the pension scheme is “incomplete,” in that benefits must be financed from outside the system, requiring additional subsidies from the government and eventually tax increases. In addition, open-system net liabilities provide a clear picture of “generational accounting”, which can help assess burden sharing between the present and future generations.

Discussions about pension liabilities remind us of a very simple strategy to improve the sustainability: “Do not promise people too much benefit to be financed.” Theoretically, there are two candidates to achieve this goal: one is a shift to a funded-DC system and the other is a shift to a pure PAYG system. In a funded-DC system, gross pension liabilities and contributions are always balanced for each generation, and so there are
effectively no net pension liabilities at all. In a pure PAYG system, the total amount of pension benefits paid out is given by the total amount of contributions. The government thus commits no future pension rights, so no liabilities exist. In both methods, however, the government has to finance the existing net pension liabilities. A funded-DC system needs additional taxes on the current and future generations, leading to no net benefit from the reform. A pure PAYG system has to reduce promised pension benefits, a solution which is not easy to be politically accepted. The concept of pension liabilities clearly points to this kind of policy dilemma.

Finally, this paper stimulates further research concerning pension liabilities. As mentioned above, the dynamic analysis seems to be of great importance in examining the sustainability of the system. Pension liabilities can also be a useful concept to analyze the intergenerational equity and intertemporal social welfare. In addition, discussions about pension liabilities emphasize the institutional aspects such as accountability and transparency, which are at the same time key concepts for a decision-making process of social security reforms.
This paper is concerned with government debt and long-term fiscal sustainability in the surveillance of budgetary positions. This paper examines the pension expenditure projections available in EU countries. This paper raises issues of international comparability and provides some solutions. In addition, this paper argues that the level of pension liabilities does not provide indications concerning the sustainability of pension schemes and their effects on public budgets and that pension liabilities should not be included in conventional debt.

I find that this paper is very informative and well thought out and that most arguments are very sensible from the practitioner’s point of view. I enjoy reading this paper very much.

I have a big comment and several small comments. A big comment is about the way in which projection is treated. In order to understand the pension position, pension expenditure projections and valuation of pension liabilities need to be calculated. But it is not, by any means, accurate forecasting of the future course of pension scheme because many elements will change in the future, i.e. discount rates, growth rate, population fertility, life expectancy, and pension scheme (contribution rate, benefits, retirement age, etc) itself. I admit that it is very important information for policy makers. Nevertheless I believe that these projections should not be taken as the future reality, it is a descriptive scenario of the future course of fiscal position if the current arrangement continues. Of course, different parameters (i.e. discount rates, growth rate, and demographic change) may provide different values; it can be examined by sensitivity analyses. As long as common parameters are used, we may be able to compare pension positions of different countries. What we can judge from these projections is the soundness of current fiscal position. If the projection shows unsustainable pension position, then the current pension scheme must be reformed somehow. The authors do not seem to provide the way in which these projections are to be used. I am interested in knowing how EU community intends to use these projections.

Some minor comments are as follows. First, the authors distinguish public debt and pension liabilities from the view point of certainty. They argue (1) while the timing of the repayment of public bonds as well as the amount to be paid to the holders is fixed in advance, those of pension liabilities is uncertain. (2) Pension rights are not embodied in formal contracts.
(3) While public bonds are usually bought freely on the market by individuals or companies, the acquisition of pension rights is usually compulsory. (4) Pension rights are not tradable. This implies that changes in the relative yield and the relative risk of pension rights comparatively to other assets have no effect on financial markets. It also implies less protection for pension right holders than for bond holders. These are very interesting observations. But pension rights are not so weak in terms of legal entitlements. Of course, the nature of entitlements differs from public bonds and pension rights, both entitlements must be fully protected by the law. I agree with the authors that the public debt and pension liabilities must be separated. It is because different nature of contracts, not because of certainty. Recall Kotlikoff’s generational accounting framework puts public debt and pension liabilities into a basket of government liabilities, the authors’ distinction of public debt and pension liabilities cast a new light on the way how to deal with different government liabilities.

Second, in their calculation, transaction (adjustment) costs, i.e. moving from PAYG to alternative scheme, may not be fully reflected. We would like to know how to calculate pension liabilities under sequences of pension reforms with transaction costs.

Third, although the authors argue that the pension rights may not affect the financial market, the pension wealth affects definitely on the financial markets. In deed, the pension fund managements become more important than before.
